Treatment of patients with cerebral salt wasting consists of restoring intravascular volume with sodium chloride and water, as for the treatment of other causes of systemic dehydration. The underlying cause of the disorder, which is usually due to acute brain injury, should also be treated if possible. Treatment involves the ongoing replacement of urine sodium losses volume for volume.

Chapter 560
Hyperpituitarism, Tall Stature, and Overgrowth Syndromes
Omar Ali

HYPERPITUITARISM
Primary hypersecretion of pituitary hormones rarely occurs in the pediatric population and should be distinguished from secondary hyperpituitarism, which occurs in the setting of target hormone deficiencies resulting in decreased hormonal feedback, such as in hypogonadism, hypoadrenalism, or hypothyroidism. In secondary hyperpituitarism, chronic pituitary hypersecretion occurs in response to target hormone deficiencies and leads to pituitary hyperplasia, which can enlarge and erode the sella and, on rare occasions, increase intracranial pressure. Such enlargements should not be confused with primary pituitary tumors; they disappear when the underlying hormone deficiency is treated. The elevated pituitary hormone levels readily suppress to normal following replacement of end-organ hormones. Pituitary hyperplasia can also occur in response to stimulation by ectopic production of releasing hormones such as that seen occasionally in patients with Cushing syndrome secondary to corticotropin-releasing hormone excess or in children with acromegaly secondary to growth hormone–releasing hormone (GHRH) produced by a variety of systemic tumors.

Primary hypersecretion of pituitary hormones by adenoma is uncommon in childhood. The most commonly diagnosed adenoma during childhood is prolactinoma, followed by corticotropinoma, and then somatotropinoma, which secrete prolactin, corticotropin, and growth hormone, respectively. There are a handful of case reports of thyrotropinoma in children and adolescents. There are no pediatric reports of gonadotropinoma, but hypothalamic hamartomas that secrete excess gonadotropin-releasing hormone are responsible for a significant proportion of cases of precocious puberty.

The monoclonal nature of most pituitary adenomas implies that most originate from a clonal event in a single cell. It is suspected that some pituitary tumors result from stimulation with hypothalamic-releasing hormones and in other instances, as in McCune-Albright syndrome (MAS), the tumor is caused by activating mutations of the GNAS1 gene that codes for the $\alpha$ subunit of $G_\alpha$, a guanine nucleotide-binding protein. The clinical presentation typically depends on the pituitary hormone that is hypersecreted. Disruptions of growth regulation and/or sexual maturation are common, as a result of either hormone hypersecretion or local compression by the tumor. MAS also features polyostotic fibrous dysplasia of bone and café-au-lait spots in a distinct distribution.

TALL STATURE
The normal distribution of height predicts that 2.3% of the population will be taller than 2 SD (97.7%) above the mean. The social acceptability and even desirability of tallness (heightism) makes tall stature an uncommon complaint in clinical practice. It is exceptionally unusual for boys and men to seek medical attention regarding excessive height. Girls (or their parents) were historically more likely to approach a physician with concern about tall stature, but even in girls this complaint has become less frequent as tallness has become more acceptable and socially desirable in adult women. Concern about side effects of estrogen treatment and reports of dissatisfaction among adult women subjected to this treatment have also led to a decline in estrogen use.

Differential Diagnosis of Tall Stature

Unusual tall stature can have different causes in each age group. Table 560-1 lists the causes of tall stature in childhood and adolescence. Figure 560-1 shows an approach to diagnosis.

Overgrowth in the Fetus and Neonate

Maternal diabetes is the most common cause of infants large for gestational age. Even in the absence of clinical symptoms or a family history, the birth of a large-for-gestational-age infant should lead to evaluation for maternal (or gestational) diabetes.

A group of disorders associated with excessive somatic growth and growth of specific organs has been described and is collectively referred to as overgrowth syndromes. These disorders appear to be caused in many cases by excess production and availability of insulin-like growth factor 2 (IGF-2) encoded by the gene Igf2. The best described of these syndromes is the Beckwith-Wiedemann syndrome (BWS), which is an overgrowth malformation syndrome that occurs with an incidence of 1:14,000 births, equal in males and females. Approximately 15% of cases are familial, while the rest appear to be sporadic. Most cases of BWS are caused by deregulation of imprinted genes within the chromosome 11p15.5 region. Genetic disruptions affecting this region include gene duplication, loss of heterozygosity, and relaxation or loss of imprinting. The “imprinted” genes involved in BWS and associated childhood tumors include, in addition to Igf2, the gene H19, which is involved in Igf2 suppression, as well as WT-1 (the Wilms tumor gene), cyclin-dependent kinase inhibitor 1C (CDKN1C), potassium channel voltage-gated KQT-like subfamily member 1 (KCNQ1), and KCNQ1-overlapping transcript 1 (KCNQ1OT1, or long QT intronic transcript 1, LIT1).

Affected infants characteristically have macrosomia including macrosomia, hepatosplenomegaly, nephromegaly, and omphalocoele. They also have hypoglycemia secondary to hyperinsulinemia as a result of pancreatic β-cell hyperplasia. Children with BWS are predisposed to a specific subset of childhood neoplasms (embryonal tumors), including Wilms tumor, hepatoblastoma, neuroblastoma, and adrenocortical carcinoma. Management focuses on omphalocoele, airway issues (a result of macroglossia), and neonatal hypoglycemia. Cancer risk is high until 8 yr of age, and regular surveillance with abdominal ultrasound and measurement of α-fetoprotein is recommended every 3 mo until age 8 yr. Thereafter, renal ultrasound is recommended every 1-2 yr as medullary sponge kidney and nephrocalcinosis may develop later.

Mutations in GPC3, a glypicin gene (which codes for an IGF-2-neutralizing membrane receptor), cause the related Simpson-Golabi-Behmel overgrowth syndrome. Other syndromic causes of fetal overgrowth include Costello syndrome, Weaver syndrome, Sotos syndrome, and Perlman syndrome.

Overgrowth in Childhood or Adolescence

Normal variant, familial, or constitutional tall stature is by far the most common cause of tall stature. Almost invariably, a family history of tall stature can be obtained, and no organic pathology is present. The child is often taller than the child’s peers throughout childhood and enjoys excellent health. The parent of the constitutionally tall adolescent might reflect unhappily upon his or her own adolescence as a tall teenager. There are no abnormalities in the physical examination, and the laboratory studies, if obtained, are negative.

Exogenous obesity is a common condition in adolescence and may be associated with rapid linear growth and early onset of puberty. Bone age is accelerated leading to relative tall stature in childhood but adult height is typically normal.

Klinefelter syndrome (XXY syndrome) is a relatively common (1 in 500-1,000 live male births) abnormality associated with tall stature, learning disabilities (including requirement for speech therapy), gynecomastia, and decreased upper body:lower body segment ratio. Affected boys can have hypotonia, clinodactyly, and hypertelorism. The testes are invariably small, although androgen production by Leydig cells is often in the low-normal range. Spermatogenesis and Sertoli cell function are defective, and infertility results. Other genital abnormalities including relatively small phallus, hypospadias, and cryptorchidism may be present.

XXY syndrome is associated with tall stature, problems in motor and language development, and possible antisocial behavior.

Marfan syndrome is an autosomal dominant connective tissue disorder consisting of tall stature, arachnodactyly, thin extremities, increased arm span, and decreased upper body:lower body segment ratio (see Chapter 702). Additional abnormalities include ocular abnormalities (e.g., lens subluxation), hypotonia, kyphoscoliosis, cardiac valvular deformities, and aortic root dilation.

Homocystinuria is an autosomal recessive inborn error of amino acid metabolism, caused by a deficiency of the enzyme cystathionine synthetase. It is characterized by intellectual disability when untreated, and many of its clinical features resemble Marfan syndrome, particularly ocular manifestations (see Chapter 85).

SOTOS SYNDROME (CEREBRAL GIGANTISM)

Children with cerebral gigantism (also known as Sotos syndrome) are above the 90th percentile for both length and weight at birth; they can also have macrocrania at that time. Most cases of Sotos syndrome are caused by mutations in the NSD1 (nuclear receptor SET domain-containing protein 1) gene, but in the Japanese population most cases are attributable to microdeletions of the 5q35 region that includes this gene. Inheritance is autosomal dominant, but 95% of cases are a result of new mutations. Incidence is estimated to be approximately 1 in 14,000 live births. The NSD1 gene is thought to play a role in epigenetic regulation, but the mechanisms by which mutations lead to the features of Sotos syndrome are not clear at this time.
Although it is characterized by rapid growth, there is no evidence that Sotos syndrome is caused by endocrine dysregulation. A hypothalamic defect has been suggested as a cause, but none has been demonstrated functionally or at necropsy. Growth is markedly rapid; by 1 yr of age, affected infants are taller than the 97th percentile in height. Accelerated growth continues for the 1st 4–5 yr and then returns to a normal rate (see Fig. 560-1). Puberty usually occurs at the expected time but may occur slightly early. Adult height is usually in the upper normal range.

Clinically, the syndrome is characterized by a large (macrocephaly) dolichocephalic head, prominent forehead and jaw, hypertelorism, antimongoloid slant of the palpebral fissures, high-arched palate, and large hands and feet with thickened subcutaneous tissue. Clumsiness and awkward gait are also noted, and affected children have great difficulty in sports, in learning to ride a bicycle, and in other tasks requiring coordination. Some degree of developmental disability affects most patients; in some affected children perceptual deficiencies may predominate. Many different types of nonfebrile seizures have been reported and up to 25% of patients with Sotos syndrome have seizures at some point in their life. Affected patients may be at somewhat increased risk for neoplasms, including neuroblastoma, hepatoblastoma, and leukemia, with a lifetime risk of between 2% and 4%. Osseous maturation is usually compatible with the patient’s height, although advanced bone age has been reported. Scoliosis develops in up to 30% of cases, usually starting in school-age children. Growth hormone (GH), IGF-1, and other endocrine studies are usually normal; there is no distinctive laboratory or radiologic marker for the syndrome. Abnormal electroencephalograms are common; imaging studies often reveal an enlarged ventricular system, but intracranial pressure is normal. Genetic testing for NSD1 mutations (or fluorescence in situ hybridization for 5q35 microdeletions in Japanese patients) is available and should be routinely used. Management is symptomatic and includes paying special attention to developmental and behavioral problems (which tend to improve with age), scoliosis, and seizure disorder. No specific treatment is needed for the overgrowth itself. There is no consensus on the need for cancer surveillance at this time.

Table 560-2 notes additional features of overgrowth syndromes.

**Hyperthyroidism** in adolescents is associated with rapid growth but normal final adult height. It is almost always caused by Graves disease and is much more common in girls (see Chapter 568).

**Precocious puberty**, whether mediated centrally (increased gonadotropin secretion) or peripherally (increased secretion of androgens or estrogens, or both), results in accelerated linear growth during childhood, mimicking the pubertal growth spurt. Because skeletal maturation is also advanced, adult height is often compromised. Chapter 562 discusses the diagnostic evaluation and management of precocious puberty.

Although **delayed puberty** may be associated with short stature in childhood, as with constitutional delay, failure to eventually enter puberty and complete sexual maturation can result in sustained growth during adult life, with ultimate tall stature. The report of tall stature with open epiphyses resulting from a mutation of the estrogen receptor in a man with normal male sexual maturation underscores the fundamental role of estrogen in promoting epiphyseal fusion and termination of normal skeletal growth. Aromatase deficiency leads to tall stature through similar pathways.
The purpose of the diagnostic evaluation of tall stature is to distinguish the commonly occurring, normal variant, constitutional variety from the rare pathologic conditions. Often, when the history suggests familial tall stature and the physical examination is entirely normal, no laboratory tests are indicated. It is valuable to obtain a bone age radiograph to be able to predict adult height, which serves as a basis for discussions with the family and for management decisions. If the history suggests any of the aforementioned disorders or the physical examination reveals abnormalities, additional laboratory tests should be obtained. IGF-1 and IGF-binding protein-3 (IGFBP-3) are excellent screening tests for GH excess and can be verified with a glucose suppression test. Laboratory evidence of GH excess mandates MRI evaluation of the pituitary. Chromosome analysis is useful in boys, especially when the ratio of upper to lower body segment is decreased or when developmental disability is present, to rule out Klinefelter syndrome. If Marfan syndrome or homocystinuria is suspected from the physical examination, referral to a cardiologist and an ophthalmologist should be made. Thyroid function tests are

useful to diagnose or rule out hyperthyroidism when this disorder is suspected.

Treatment of Normal Variant Tall Stature

Reassurance of the family and the patient is the key to the management of normal variant tall stature. The use of the bone age to predict adult height might provide some comfort for them, as will general supportive discussions on the social acceptability of this condition. Although treatment is possible for girls and boys with excessive growth, its use should be restricted to patients with predicted adult height >3.4 SD above the mean (79 inches or 200 cm in boys, 73 inches or 185 cm in girls) and evidence of significant psychosocial impairment.

Sex steroids have been used in the treatment of tall stature and are designed to accelerate puberty and to promote epiphyseal fusion; these are therefore of little benefit when given in late puberty. The lack of extensive experience with this form of therapy and the risks of estrogen or androgen treatment for tall stature should be carefully weighed and discussed with the family and treatment should be discouraged except in the most extreme cases. Detailed discussion with the child at the child's level is also advisable as up to 40% of those who underwent such treatments are dissatisfied as adults and feel they were not sufficiently consulted about this course of action. Therapy is initiated ideally before puberty or in early puberty. In boys, treatment should begin before the bone age reaches 14 yr. In the extremely rare instances where treatment is desired, testosterone enanthate is used at a dose of 500 mg intramuscularly every 2 wk for 6 mo. In girls, oral estrogens in various doses have been used to reduce the predicted height, but average height reduction may be only 1.1-2.4 cm. Therapy must begin before the bone age has reached 12 yr. In the rare case where treatment is advised, oral ethinyl estradiol at a dose of 0.15-0.5 mg/day until cessation of growth occurs has been used. Short-term side effects have included benign breast disease, cholelithiasis, hypertension, menstrual irregularities, weight gain, nausea, limb pain, galactorrhea, and thrombosis. Reduced fertility later in life may be a potential long-term complication.

EXCESS GROWTH HORMONE SECRETION AND PITUITARY GIGANTISM

In young persons with open epiphyses, overproduction of GH results in gigantism; in persons with closed epiphyses, the result is acromegaly. Often some acromegalic features are seen with gigantism, even in children and adolescents. After closure of the epiphyses, the acromegalic features become more prominent.

Gigantism is rare, with only several hundred reported cases to date. Most cases are sporadic and are caused by pituitary adenomas or excessive GHRIH secretion by the hypothalamus (and, rarely, by tumors in other parts of the body). Syndromes associated with pituitary GH excess include MAS, which is caused by mutations resulting in constitutively activated G-proteins, and can include somatotrophic tumors and excess GH secretion. Approximately 20% of patients with gigantism have MAS (commonly consisting of a triad of precocious puberty, café-au-lait spots, and fibrous dysplasia) and 20% of patients with MAS have some degree of GH hypersecretion. GH-secreting tumors are seen in approximately 60% of patients with multiple endocrine neoplasia type 1, but almost all these tumors develop in adult life and cause acromegaly rather than pituitary gigantism. Increased GH secretion and GH-secreting adenomas may also be seen in neurofibromatosis, tuberous sclerosis, and Carney complex.

The cardinal clinical feature of gigantism is longitudinal growth acceleration secondary to GH excess. The usual manifestations consist of coarse facial features and enlarging hands and feet. In young children, rapid growth of the head can precede linear growth. Some patients have behavioral and visual problems. In most recorded cases, the abnormal growth became evident at puberty, but the condition has been established as early as the newborn period in 1 child and at 21 mo of age in another. Giants have rarely been reported to grow to a height of over 8 ft. In some cases the patient may present with local effects of the pituitary tumor (headache, visual field defects, and other pituitary hormone deficiencies) as the main complaint, and there is at least 1 report of a patient presenting with diabetic ketoacidosis induced by GH excess. The presentation of gigantism is usually dramatic, unlike the insidious onset of acromegaly in adults.

Approximately 50% of the pituitary adenomas that cause gigantism also exhibit hyperprolactinemia because they secrete both GH and prolactin. This is because mammomosomatotrophs are the most common type of GH-secreting cells involved in childhood gigantism. GH-secreting tumors of the pituitary are typically eosinophilic or chromophobic adenomas. Adenomas can compromise other anterior pituitary function through growth or cystic degeneration. Secretion of gonadotropins, thyrotropin, or corticotropin may be impaired. Delayed sexual maturation or hypogonadism can occur. When GH hypersecretion is accompanied by gonadotropin deficiency, accelerated linear growth can persist for decades. In some cases, the tumor spreads outside the sella, invading the sphenoid bone, optic nerves, and brain. GH-secreting tumors in pediatric patients are more likely to be locally invasive or aggressive than are those in adults.

Acromegalic features consist chiefly of enlargement of the distal parts of the body, but manifestations of abnormal growth involve all portions. The circumference of the skull increases, the nose becomes broad, and the tongue is often enlarged, with coarsening of the facial features. The mandible grows excessively, and the teeth become separated. Visual field defects and neurologic abnormalities are common; signs of increased intracranial pressure appear later. The fingers and toes grow chiefly in thickness. There may be dorsal kyphosis. Fatigue and lassitude are early symptoms. GH levels are elevated and occasionally exceed 100 ng/mL. There is usually no suppression of GH levels by the hyperglycemia of a glucose tolerance test and IGF-1 and IGFBP-3 levels are consistently elevated in acromegaly and pituitary gigantism.

Diagnosis

Most children with tall stature do not have pituitary gigantism and other etiologies of rapid linear growth such as genetic tall stature, precocious puberty, and hyperthyroidism should be carefully excluded. Coexisting findings (e.g., dysmorphic facial features, neurocognitive problems, hemihypertrophy) may suggest syndromic or chromosomal causes of tall stature, such as Sotos, Weaver, Klinefelter, or XYY syndrome. GH hypersecretion can be screened for by testing IGF-1 and IGFBP-3 levels. An excellent linear dose–response correlation between serum IGF-1 levels and 24 hr mean GH secretion has been demonstrated. An elevated IGF-1 level in a patient with appropriate clinical suspicion usually indicates GH excess. Potential confusion can arise in the evaluation of normal adolescents because significantly higher IGF-1 levels occur during puberty than in adulthood, so the IGF-1 level must be age and gender matched. Serum IGFBP-3 levels are also sensitive markers of GH elevations and will be elevated in almost all cases. If IGF-1 and/or IGFBP-3 levels are elevated, then the next step is to test for GH excess by doing an oral glucose-suppression test. The gold standard for the diagnosis of GH excess in adults is the failure to suppress serum GH levels to <1 ng/dL at any time during a 2 hr oral glucose tolerance test with 1.75 g/kg oral glucose challenge (maximum: 75 g). GH levels may not be suppressed to this level in normal adolescents and a cutoff of 5 ng/mL may be more appropriate in this age group. If laboratory findings suggest GH excess, the presence of a pituitary adenoma should be confirmed by MRI of the brain. In rare cases, a pituitary mass is not identified. This might be from an occult pituitary microadenoma or ectopic production of GHRIH or GH. CT is acceptable when MRI is unavailable.

Treatment

The goals of therapy are to remove or shrink the pituitary mass, to restore GH and secretory patterns to normal, to restore IGF-1 and IGFBP-3 levels to normal, to retain the normal pituitary secretion of other hormones, and to prevent recurrence of disease.

For well-circumscribed pituitary adenomas, transphenoidal surgery is the treatment of choice and may be curative. The tumor should be removed completely. The likelihood of surgical cure depends greatly on the surgeon's expertise as well as on the size and extension of the mass. Intraoperative GH measurements can improve the results of tumor resection. Transphenoidal surgery to resect the tumors is as
safe in children as in adults. At times, a transcranial approach might be necessary. The primary goal of treatment is to normalize GH and IGF-1 levels. GH levels (<1 ng/mL within 2 hr after a glucose load) and serum IGF-1 levels (age-adjusted normal range) are the best tests to define a biochemical cure.

If GH secretion and IGF-1 levels are not normalized by surgery, the options include pituitary irradiation and medical therapy. Further growth of the tumor is prevented by irradiation in >99% of patients. The main disadvantage is the delayed efficacy in decreasing GH levels. GH is reduced by approximately 50% from the initial concentration by 2 yr, by 75% by 5 yr, and approaches 90% by 15 yr. Multiple pituitary hormone deficiencies is a predictable outcome, occurring in 40-50% of patients 10 yr after irradiation.

Surgery fails to cure a significant number of patients and radiotherapy may not work fast enough, so medical therapy has an important role in treating patients with GH excess. Treatment is effective and well tolerated with long-acting somatostatin analogs and dopamine agonists, as well as novel GH antagonists.

The somatostatin analogs are highly effective in the treatment of patients with GH excess. Octreotide suppresses GH to <2.5 ng/mL in 65% of patients with acromegaly and normalizes IGF-1 levels in 70%. The effects of octreotide are well sustained over time. Tumor shrinkage also occurs with octreotide but is generally modest. Consistent GH suppression can be obtained with a continuous SC pump infusion of octreotide or with long-acting formulations, including long-acting octreotide and lanreotide. These produce consistent GH and IGF-1 suppression in acromegalic patients with once-monthly or biweekly IM depot injections. These sustained-release preparations have not been formally tested in children. Octreotide injection in the pediatric population has been used at doses of 1-40 μg/kg/24 hr. In adults the long-acting form is used in a dose of 10-40 mg every mo, but no pediatric dose range has been established.

For patients with both GH and prolactin oversecretion, dopamine agonists, such as bromocriptine and cabergoline, which bind to pituitary dopamine type 2 receptors and may also suppress GH secretion, should be considered. Prolactin levels are often adequately suppressed, but GH levels and IGF-1 levels are rarely normalized with this treatment modality alone. Tumor shrinkage occurs in a minority of patients. The effectiveness of these agents may be additive to that of octreotide. Cabergoline therapy at doses of 0.25-4.0 mg/wk (given 1-2 times per wk) has been used in adults with acromegaly, and because of its less-frequent dosing and lower incidence of side effects as compared to bromocriptine, this is now considered the dopamine agonist of choice in both adults and children.

Side effects can include nausea, vomiting, abdominal pain, arrhythmias, nasal stuffiness, orthostatic hypotension, sleep disturbances, and fatigue.

Pegvisomant is a GH-receptor antagonist that competes with endogenous GH for binding to the GH receptor. It effectively suppresses GH and IGF-1 levels in patients with acromegaly caused by pituitary tumors as well as ectopic GHRR hypersecretion. Normalization of IGF-1 levels occurs in up to 90% of patients treated daily with this drug for 3 mo or longer. The adult dosage is 10-40 mg via subcutaneous injection once daily, although twice-weekly protocols have also been reported as highly successful. IGF-1 levels and hepatic enzymes must be monitored. Combined therapy with somatostatin analogs and pegvisomant injections also is effective. Pediatric experience is limited, but case reports indicate that it can successfully suppress IGF-1 levels when used in doses of 10-30 mg/day.

Corticotropinoma
Corticotropinoma is very rare in children, and its peak occurrence is at age 14 yr. Cushing disease refers specifically to an adrenocorticotrophic hormone–producing pituitary adenoma that stimulates excess cortisol production and secretion. It is more common than primary adrenal causes of Cushing syndrome, except in younger children (younger than 5 yr of age), in whom adrenal carcinomas and adrenal activating mutations of MAS are rare but dominant causes of the syndrome. Adenomas causing Cushing disease are almost always microadenomas with a diameter of <5 mm and are significantly smaller than all other types of adenomas at presentation. The most sensitive indicator of excess glucocorticoid secretion in children is growth failure, which generally precedes other manifestations. Patients develop weight gain that tends to be centripetal rather than generalized. Pubertal arrest, hypertension, large purplish striae, fatigue, and depression are also common. In prepubertal children, males are more frequently affected than females.

Midnight salivary cortisol measurements can be used as a screening test for cortisol excess, but confirmation requires at least 1 additional test (either 24 hr urinary free cortisol or an overnight dexamethasone suppression test). Location of the microadenoma is usually determined by MRI, and bilateral inferior petrosal sinus sampling may be needed in difficult cases. Transphenoidal surgery is the treatment of choice for Cushing disease in children. Initial remission rates of 70-98% of patients and long-term success rates of 50-98% are reported. Residual transient hypoadrenalinism is often observed after surgery, lasting as
long as 30 mo. Pituitary radiotherapy is used if cortisol levels remain elevated and/or adrenocorticotropic hormone levels continue to be detectable. Successful treatment may not correct the height deficit, and GH deficiency may be present after treatment and should be treated as required.

Bibliography
Between early childhood and approximately 8-9 yr of age (prepubertal stage), the hypothalamic-pituitary-gonadal axis is dormant, as reflected by undetectable serum concentrations of luteinizing hormone (LH) and sex hormones (estradiol in girls, testosterone in boys). One to 3 yr before the onset of clinically evident puberty, low serum levels of LH during sleep become demonstrable. This sleep-entrained LH secretion occurs in a pulsatile fashion and reflects endogenous episodic discharge of hypothalamic gonadotropin-releasing hormone (GnRH). Nocturnal pulses of LH continue to increase in amplitude and, to a lesser extent, in frequency as clinical puberty approaches. This pulsatile secretion of gonadotropins is responsible for enlargement and maturation of the gonads and the secretion of sex hormones. The appearance of the secondary sex characteristics in early puberty is the visible culmination of the sustained, active interaction occurring among hypothalamus, pituitary, and gonads in the peripubertal period. By midpuberty, LH pulses become evident even during the daytime and occur at approximately 90-120 min intervals. A second critical event occurs in middle or late adolescence in girls in whom cyclicity and ovulation occur. A positive feedback mechanism develops whereby increasing levels of estrogen in midcycle cause a distinct increase of LH.

The increasing secretion of hypothalamic GnRH in a pulsatile fashion thus underlies the onset of pubertal development. The resulting "GnRH pulse generator" is regulated by multiple neuropeptides, including glutamic acid, kisspeptin, and neuropeptide Y (stimulatory) and γ-aminobutyric acid, preproenkephalin, and dynorphin (inhibitory). GnRH secretion is also regulated by factors produced by the glial cells, such as transforming growth factor α. Loss-of-function mutations of the KISS1 R—also known as GPR54—gene (the gene encoding a G-protein–coupled receptor whose ligand is kisspeptin) cause an autosomal recessive form of hypogonadotropic hypogonadism, whereas gain-of-function mutations of the gene are associated with precocious puberty. Increased transforming growth factor α signaling is associated with the occurrence of central precocious puberty in patients with hypothalamic hamartoma.

The interpretation of the hormonal changes of puberty is complex. Issues in interpreting LH and follicle-stimulating hormone measurements include the presence of multiple gonadotropin isoforms, immunoassay-related variability, and problems inherent to their pulsatile secretion, which mandates serial sampling in plasma. In addition, important sex differences exist in the maturation of the hypothalamus and pituitary gland, and serum LH concentrations tend to increase earlier in the course of the pubertal process in boys than in girls. Adrenocortical androgens also have a role in sexual maturation. Serum levels of dehydroepiandrosterone (DHEA) and its sulfate (DHEAS) begin to increase at approximately 6-8 yr of age, before any increase in LH or sex hormones and before the earliest physical changes of puberty are apparent; this process is called adrenarche. DHEAS is the most abundant adrenal C-19 steroid in the blood, and its serum concentration remains fairly stable over 24 hr. A single measurement of this hormone is commonly used as a marker of adrenal androgen secretion. Although adrenarche typically antedates the onset of gonadal activity (gonadarche) by a few years, the 2 processes do not seem to be causally related, because adrenarche and gonadarche are dissociated in conditions such as central precocious puberty and adrenocortical failure.

The effects of gonadal steroids (testosterone in boys, estradiol in girls) on bone growth and osseous maturation are critical. Both aromatase deficiency and estrogen receptor defects result in delayed epiphyseal fusion and tall stature in affected males. These observations suggest that estrogens, rather than androgens, are responsible for the process of bone maturation that ultimately leads to epiphyseal fusion and cessation of growth. Estrogens also mediate the increased production of growth hormone, which along with a direct effect of sex steroids on bone growth, is responsible for the pubertal growth spurt.

The age of onset of puberty varies and is more closely correlated with osseous maturation than with chronological age (see Chapter 14). In females, the breast bud (thelarche) is usually the first sign of puberty (10-11 yr of age), followed by the appearance of pubic hair (pubarche) 6-12 mo later. The interval to the onset of menstrual activity (menarche) is usually 2-2.5 yr, but may be as long as 6 yr. In the United States, at least 1 sign of puberty is present in approximately 95% of girls by 12 yr of age and in 99% of females by 13 yr of age. Peak height velocity occurs early (at breast stages II-III, typically between 11 and 12 yr of age) in girls and always precedes menarche. The mean age of menarche is approximately 12.75 yr. There are, however, wide variations in the sequence of changes involving growth spurt, breast bud, pubic hair, and maturation of the internal and external genitalia.

In males, growth of the testes (≥4 mL in volume or 2.5 cm in longest diameter) and thinning of the scrotum are the first signs of puberty (11-12 yr). These are followed by pigmentation of the scrotum and growth of the penis (see Chapter 14) and by pubarche. Appearance of axillary hair usually occurs in midpuberty. In males, unlike in females, acceleration of growth begins after puberty is well under way and is maximal at genital stages IV-V (typically between 13 and 14 yr of age). In males, the growth spurt occurs approximately 2 yr later than in females, and growth may continue beyond 18 yr of age.

Genetic and environmental factors affect the timing for the onset of puberty. Population-based studies in the United States and in Europe suggest secular trends for earlier onset of puberty over the past few decades in females and, to a lesser degree, in males. African-American and, to a lesser extent, Hispanic girls appear to be more advanced in the development of secondary sex characteristics for age than white females. The timing of menarche has, however, remained generally stable with only a marginal advancement (2.5-4 mo) reported in U.S.-based studies and no significant change reported in the Copenhagen Puberty Study. The latter also showed that the earlier onset of breast development observed in girls examined in 2006-2008 when compared to those seen in 1991-1993 (means: 10.88 yr vs 9.86 yr, p < 0.0001) was not associated with different levels of estradiol or gonadotropins when girls of similar chronological ages were compared between the 2 groups. Hence, earlier breast development may not necessarily reflect an earlier activation of the hypothalamic-pituitary-gonadal axis but could be the consequence of other factors such as increased adiposity or increased exposure to certain environmental agents. Positive correlations between the degree of adiposity and earlier pubertal development in girls have, indeed, been reported. Conversely, female athletes in whom leanness and strenuous physical activity have coexisted from early childhood frequently exhibit a marked delay in puberty or menarche, and they frequently have oligomenorrhea or amenorrhea as adults (see Chapter 691). Pubertal delay is also prevalent in males who are physically very active. These observations support the thesis that the energy balance is closely related to the activity of the GnRH pulse generator and the mechanisms initiating and sustaining puberty via hormonal signals such as leptin or other adipokines.

Bibliography

Precocious puberty is defined by the onset of secondary sexual characteristics before the age of 8 yr in girls and 9 yr in boys. The variation in the age of the onset of puberty in normal children, particularly of different ethnicities, makes this definition somewhat arbitrary. It remains in use by most clinicians.

Depending on the primary source of the hormonal production, precocious puberty may be classified as central (also known as gonadotropin dependent, or true) or peripheral (also known as gonadotropin independent or precocious pseudopuberty) (Table 562-1). **Central** precocious puberty is always isosexual and stems from hypothalamic-pituitary-gonadal activation with ensuing sex hormone secretion and progressive sexual maturation. In **peripheral** precocious puberty, some of the secondary sex characteristics appear, but there is no activation of the normal hypothalamic-pituitary-gonadal interplay. In this latter group, the sex characteristics may be isosexual or heterosexual (contrasexual) (see Chapters 583-588).

Peripheral precocious puberty can induce maturation of the hypothalamic-pituitary-gonadal axis and trigger the onset of central puberty. This mixed type of precocious puberty occurs commonly in conditions such as congenital adrenal hyperplasia, McCune-Albright syndrome, and familial male-limited precocious puberty, when the bone age reaches the pubertal range (10.5-12.5 yr).

### 562.1 Central Precocious Puberty

**Luigi R. Garibaldi and Wassim Chemaitilly**

Central precocious puberty is defined by the onset of breast development before the age of 8 yr in girls and by the onset of testicular development (volume ≥4 mL) before the age of 9 yr in boys, as a result of the early activation of the hypothalamic-pituitary-gonadal axis. It occurs 5-10-fold more frequently in girls than in boys and is usually sporadic. A high prevalence of idiopathic central precocious puberty has been reported in girls adopted from developing countries, with the limitation that the exact date of birth may be uncertain.

Although approximately 90% of girls have an idiopathic form, a structural central nervous system (CNS) abnormality can be demonstrated in up to 75% of boys with central precocious puberty. Beyond its etiology, which thus needs to be specifically addressed, central precocious puberty can impact linear growth and affect the child’s growth potential.

#### CLINICAL MANIFESTATIONS

Sexual development may begin at any age and generally follows the sequence observed in normal puberty. In girls, early menstrual cycles may be more irregular than they are with normal puberty. The initial cycles are usually anovulatory, but pregnancy has been reported as early as 5.5 yr of age (Fig. 562-1). In boys, testicular biopsies have shown stimulation of all elements of the testes, and spermatogenesis has been observed as early as 5-6 yr of age. In affected girls and boys, height, weight, and osseous maturation are advanced. The increased rate of bone maturation results in early closure of the epiphyses, and the ultimate stature is less than it would have been otherwise. Without treatment, approximately 30% of girls and an even larger percentage of boys achieve a height less than the 5th percentile as adults. Mental development is usually compatible with chronological age. Emotional behavior and mood swings are common, but serious psychologic problems are rare.

Although the clinical course is variable, 3 main patterns of pubertal progression can be identified. Most girls (particularly those younger than 6 yr of age at the onset) and a large majority of boys have rapidly progressive puberty, characterized by rapid physical and osseous maturation, leading to a loss of height potential. An increasing percentage of girls (older than 6 yr of age at the onset with an idiopathic form) have a slowly progressive variant, characterized by parallel advancement of osseous maturation and linear growth, with preserved height potential. Spontaneously regressive or unsustained central precocious

*Central puberty without true gonadotropin dependency (see text) hCG, human chorionic gonadotropin; SCTAT, sex-cord tumor with annular tubules.
satile secretion of LH. Intravenous administration of gonadotropin-releasing hormone (GnRH stimulation test) or a GnRH agonist (leuprolide stimulation test) is a helpful diagnostic tool, particularly for boys, in whom a “pubertal” LH response (LH peak >5 IU/L) with predominance of LH over follicle-stimulating hormone (FSH) tends to occur early in the course of precocious puberty. In girls with sexual precocity, however, the nocturnal LH secretion and the LH response to GnRH or GnRH agonist may be quite low at breast stages II to early III (immunometric LH peak, <5 IU/L), and the LH:FSH ratio may remain low until mid-advanced puberty. In such girls with “low” LH response, the central nature of sexual precocity can be proven by detecting pubertal levels of estradiol (>50 pg/mL), 20-24 hr after stimulation with leuprolide.

Osseous maturation is variably advanced, often by more than 2-3 SD. Pelvic ultrasonography in girls reveals progressive enlargement of the ovaries, followed by enlargement of the fundus and then of the whole uterus to pubertal size. An MRI scan usually demonstrates physiologic enlargement of the pituitary gland, as seen in normal puberty; it may also reveal CNS pathology (see Chapter 562.2).

DIFFERENTIAL DIAGNOSIS
Organic CNS causes of central sexual precocity are more likely in boys, and those girls who have rapid breast development, have estradiol...
Gonadotropin-independent causes of iatrogenic precocious puberty must be considered in the differential diagnosis (see Table 562-1). For girls, these include tumors of the ovaries, autonomously functioning ovarian cysts, feminizing adrenal tumors, McCune-Albright syndrome, and exogenous sources of estrogens. In boys, congenital adrenal hyperplasia, adrenal tumors, Leydig cell tumors, chorionic gonadotropin-producing tumors, exposure to exogenous androgens, and familial male precocious puberty should be considered.

**TREATMENT**

Virtually all boys and the large subgroup of girls with rapidly progressive precocious puberty are candidates for treatment. Girls with slowly progressive idiopathic central precocious puberty do not seem to benefit in terms of height prognosis from GnRH-agonist therapy. Former small-for-gestational-age infants may be at greater risk of short stature as adults and may require more aggressive treatment of precocious puberty, possibly in conjunction with human growth hormone therapy. Certain parents require treatment solely for psychologic or social reasons, including children with special needs and very young girls at risk of early menarche.

The observation that the pituitary gonadotropic cells require pulsatile, rather than continuous, stimulation by GnRH to maintain the ongoing release of gonadotropins provides the rationale for using GnRH agonists for treatment of central precocious puberty. By virtue of being more potent, and having a longer duration of action, than native GnRH, these GnRH agonists (after a brief period of stimulation) "desensitize" the gonadotropic cells of the pituitary to the stimulatory effect of endogenous GnRH and effectively halt the progression of central sexual precocity.

Long-acting formulations of GnRH agonists, which maintain fairly constant serum concentrations of the drug for weeks or months, constitute the preparations of choice for treatment of central precocious puberty. In the United States, the available preparations include: (1) leuprolide acetate (Lupron Depot-Ped), in a dose of 0.25-0.3 mg/kg (minimum 7.5 mg) intramuscularly once every 4 wk; (2) longer-acting preparations of depot leuprolide, allowing for injections (11.25-30.0 mg intramuscularly) every 90 days; and (3) histrelin (Supprelina LA), a subcutaneous 50 mg implant with effects lasting 12 mo. Other preparations (D-Trp6-GnRH [Decapeptyl], goserelin acetate [Zoladex]) are approved for treatment of precocious puberty in other countries. Recurrent sterile fluid collections at the sites of injections are an uncommon local side effect and occur in less than 1-3% of patients treated with depot leuprolide. Breakage or malfunction of the histrelin implant is very rare. Other available treatment options, usually reserved for children who cannot tolerate the products listed above, include subcutaneous injections of aqueous leuprolide, given once or twice daily (total dose 60 μg/kg/24 hr), or intranasal administration of the GnRH agonist nafarelin (Synarel), 800 μg bid. The potential for irregular compliance with daily administration, as well as the variable absorption of the intranasal route for nafarelin, may limit the long-term benefit of the latter preparations on adult height. GnRH antagonists are not FDA approved. Oral GnRH antagonists are also being investigated.

Treatment results in decrease of the growth rate, generally to age-appropriate values, and an even greater decrease of the rate of osseous maturation. Some children, particularly those with greatly advanced (pubertal) bone age, may show marked deceleration of their growth rate and a complete arrest in the rate of osseous maturation. Treatment results in enhancement of the predicted height, although the actual adult height of patients followed to epiphyseal closure is approximately 1 SD less than their midparental height. In girls, breast development may regress in those with Tanner stages II—III development. Most commonly, the size of the breasts remains unchanged in girls with stages III—V development, or may even increase slightly because of progres-
should be considered for patients with associated growth hormone deficiency.

562.3 Precocious Puberty Following Irradiation of the Brain
Wassim Chemaitilly and Luigi R. Garibaldi

Radiation therapy, generally for leukemia or intracranial tumors, increases the risk of precocious puberty considerably. Whether the irradiation is directed to the hypothalamic area or to areas of the brain anatomically distant from the hypothalamus. Low-dose radiation (18-24 Gy) hastens the onset of puberty almost exclusively in girls. High-dose radiation (25-47 Gy), conversely, appears to trigger precocious sexual development in both sexes, and the risk of sexual precocity is inversely proportional to the age of the child at the time radiation was given.

This type of sexual precocity is often associated with growth hormone deficiency and may also be combined with other conditions (spinal irradiation, hypothyroidism) adversely affecting the prognosis for a reasonable adult height. Unless careful attention is paid to early signs of pubertal development in these children, the combination of growth hormone deficiency and the growth-promoting effect of sex steroids often results in a “normal” growth rate at the expense of a rapidly advancing bone age and impaired adult height potential.

TREATMENT
GnRH analogs are effective in arresting pubertal progression in this patient population. However, concomitant growth hormone deficiency (and/or thyroid hormone deficiency) should be diagnosed and treated promptly in order for the adult height prognosis to improve.
Paradoxically, hypopituitarism with gonadotropin deficiency may subsequently develop as a late effect of high-dose CNS irradiation in patients with or without a history of precocious puberty, and it may require substitution therapy with sex steroids.

562.4 Syndrome of Precocious Puberty and Hypothyroidism

Luigi R. Garibaldi and Wassim Chemaitilly

In children with untreated hypothyroidism, the onset of puberty is usually delayed until epiphyseal maturation reaches 12-13 yr of age. Precocious puberty in a child with untreated hypothyroidism and a prepubertal bone age presents a strikingly unphysiologic association, yet is common and may occur in as many as 50% of children with severe hypothyroidism of long duration. These children have the usual manifestations of hypothyroidism, including retardation of growth and of osseous maturation (see Chapter 565). The cause of the hypothyroidism is usually Hashimoto thyroiditis, which often goes undiagnosed, especially in children with special needs such as those with trisomy 21, in whom the symptoms of profound hypothyroidism may be more difficult to recognize. Sexual development in girls consists of breast enlargement and menstrual bleeding; the latter may occur even in girls with minimal breast enlargement. Pubic hair development occurs with modest or no penile enlargement. No pubic hair development occurs in boys, with the average age of onset of 2 yr. An enlarged liver or mass in the right upper quadrant (testicular volume >30 mL) may persist in adult males despite adequate levothyroxine therapy.

562.5 Chorionic Gonadotropin-Secreting Tumors

Luigi R. Garibaldi and Wassim Chemaitilly

These are rare tumors, whose secretion of hCG stimulates the LH receptors in the Leydig cells. The testicles are only minimally enlarged, and the histology reveals interstitial cell hyperplasia with no spermatogenesis. Plasma levels of testosterone are elevated, while those of FSH and LH, as measured by specific immunometric assays, are low. These tumors induce puberty in boys but not in girls, as ovarian production of estrogens cannot take place in the absence of FSH stimulation.

HEPATIC TUMORS

All reported cases of hepatoblastoma causing isosexual precocious puberty have been in boys, with the average age of onset of 2 yr (range: 4 mo to 8 yr). An enlarged liver or mass in the right upper quadrant should suggest the diagnosis. Plasma levels of hCG and α-fetoprotein are usually markedly elevated and serve as useful markers for following the effects of therapy. Similarly to other carcinomas of the liver, the prognosis for survival beyond 1-2 yr from the time of diagnosis is poor.

562.6 McCune-Albright Syndrome

(Wassim Chemaitilly and Luigi R. Garibaldi)

This syndrome of endocrine dysfunction is associated with patchy cutaneous pigmentation and fibrous dysplasia of the skeletal system. It is a rare condition with a prevalence between 1 in 100,000 and 1 in 1,000,000 people. A classical cause of peripheral precocious puberty, it can also induce pituitary, thyroid, and adrenal aberrations. It is characterized by autonomous hyperfunction of many glands and is caused by a missense mutation in the gene encoding the α-subunit of Gs, the G protein that stimulates cyclic adenosine monophosphate formation, resulting in the formation of the putative gsp oncoprotein. Activation of receptors (corticotropin [adrenocorticotropic hormone (ACTH)], TSH, FSH, and LH receptors) that operate via a cyclic adenosine monophosphate–dependent mechanism, as well as cell proliferation, ensue. Because the mutation is somatic rather than genomic, it is expressed differently in different tissues; hence the variability of clinical expression. Precocious puberty has been described predominantly in girls (Fig. 562–4). The average age at onset in affected girls is about 3 yr, but vaginal bleeding has occurred as early as 4 mo of age and secondary sex characteristics have occurred as early as 6 mo. Young girls have suppressed levels of LH and FSH, and there is no response to GnRH or leuprolide stimulation. Estradiol levels vary from normal to markedly elevated (>900 pg/mL), are often cyclic, and may correlate with the size of the recurrent ovarian cysts. In boys, precocious puberty is less common but has been reported in several instances. Unlike ovarian enlargement in girls, testicular enlargement in boys is fairly symmetric. It is followed by the appearance of phallic enlargement and pubic hair, as in normal puberty. Testicular histology has demonstrated large seminiferous tubules and no or minimal Leydig cell hyperplasia; these findings may simply reflect the fact that biopsy specimens were obtained at an early stage of pubertal development. In girls and boys, when the bone age reaches the usual pubertal age range, gonadotropin secretion begins, and the response to GnRH becomes pubertal. Central precocious puberty overrides the antecedent (gonadotropin-independent) precocious pseudopuberty. In girls, menses become more regular, but often not completely so, and fertility has been documented.

Pubertal progression is variable in these patients. Functioning ovarian cysts often disappear spontaneously; aspiration or surgical excision of cysts is rarely indicated, but ovarian torsion may occur.
Of the extraglandular manifestations, phosphaturia, leading to rickets or osteomalacia, is the most common. Cardiovascular and hepatic involvement is rare but may be life-threatening (severe neonatal cholestasis).

### 562.7 Familial Male Gonadotropin-Independent Precocious Puberty

**Wassim Chemaitilly and Luigi R. Garibaldi**

This rare, autosomal dominant form of peripheral precocious puberty is transmitted from affected males and unaffected female carriers of the gene to their male offspring. Signs of puberty appear by 2-3 yr of age. The testes are only slightly enlarged. Testicular biopsies show Leydig cell maturation and, sometimes, marked hyperplasia. Maturity of seminiferous tubules may be present. Testosterone levels are variably and often markedly elevated, even above the adult male range; however, baseline levels of LH are prepubertal, pulsatile secretion of LH is absent, and LH does not respond to stimulation with GnRH or GnRH agonist. The cause for activation of Leydig cells independently of gonadotropin stimulation is a missense mutation of the LH receptor leading to constitutive activation of cyclic adenosine monophosphate production. Osseous maturation may be markedly advanced; when it reaches the pubertal age range, hypothalamic maturation shifts the mechanism of pubertal development to a gonadotropin-dependent one. This sequence of events is similar to that occurring in children with McCune-Albright syndrome (see Chapter 562.6) or in those with congenital adrenal hyperplasia (see Chapter 576.1).

Gonadotropin-independent precocious puberty has been diagnosed in a few unrelated boys with type IA pseudohypoparathyroidism who had a single mutation of the Gα protein. This mutation is inactivating at normal body temperature and causes pseudohypoparathyroidism, but in the cooler temperature of the testes, it is constitutionally activating, resulting in adenyl cyclase stimulation and production of testosterone. Although this mutation differs from the constitutive LH receptor mutation, which usually causes familial male gonadotropin-independent precocious puberty, the end result is the same.

#### TREATMENT

Young boys have been successfully treated with ketoconazole (600 mg/24 hr in 8 hr divided doses), an antifungal drug that inhibits C-17,20-lyase and testosterone synthesis. Other investigators use a combination of antiandrogens (such as spironolactone 50-100 mg bid, flutamide 125-250 mg bid, or bicalutamide 25-50 mg daily) and aromatase inhibitors (letrozole 2.5 mg/day, or anastrozole 1 mg/day), because estrogens derived from androgens stimulate bone maturation. These medications are unable to revert the serum testosterone to the normal (prepubertal) concentrations or completely offset the unfavorable effects of the elevated sex hormones. They slow down, but do not halt, the progression of puberty and may not improve the height prognosis. Boys whose GnRH pulse generator has matured require combined therapy with GnRH agonists.

### 562.8 Incomplete (Partial) Precocious Development

**Luigi R. Garibaldi and Wassim Chemaitilly**

Isolated manifestations of precocity without development of other signs of puberty are not unusual; development of the breasts in girls and growth of sexual hair in both sexes are the 2 most common forms.
PREMATURE THELARCHE

This term applies to a sporadic, transient condition of isolated breast development that most often appears in the 1st 2 yr of life. In some girls, breast development is present at birth and persists. It may be unilateral or asymmetric and often fluctuates in degree. Growth and osseous maturation are normal or slightly advanced. The genitalia show no evidence of estrogenic stimulation. Breast development may regress after 2 yr, often persists for 3-5 yr, and is rarely progressive. Menarche occurs at the expected age, and reproduction is normal. Basal serum levels of FSH and the FSH response to GnRH stimulation may be greater than that seen in normal controls. Plasma levels of LH and estradiol are consistently less than the limits of detection. Ultrason sound examination of the ovaries reveals normal size, but a few small (<9 mm) cysts are not uncommon.

In some girls, breast development may be associated with definite evidence of systemic estrogen effects, such as growth acceleration or bone age advancement. Pelvic sonography may reveal enlarged ovaries or uterus. This condition, referred to as exaggerated or atypical the larche, differs from central precocious puberty because it spontaneously regresses. Leuprolide or GnRH stimulation elicits a robust FSH response, a low LH response, and (after leuprolide only) a moderate estradiol increment at 24 hr (average: 60-90 pg/mL). The pathogenesis of typical and exaggerated forms of thelarche is unclear. Delayed inactivation of the hypothalamic-pituitary-ovarian axis, which is active during the prenatal and early postnatal period, increased peripheral sensitivity to estrogens, and other possibilities have been proposed, yet are unproven hypotheses. Premature thelarche is a benign condition but may be the first sign of true or peripheral precocious puberty, or it may be caused by exogenous exposure to estrogens. In addition to a detailed history, a bone age should be obtained if there are any unusual features. Random serum concentrations of FSH, LH, and estradiol are generally low and not diagnostic. Pelvic ultrasound examination or leuprolide stimulation testing is rarely indicated. Continued observation is important because the condition cannot be readily distinguished from true precocious puberty. Regression and recurrence suggest functioning follicular cysts. Occurrence of thelarche in children older than 3 yr of age most often is caused by a condition other than benign premature thelarche.

PREMATURE PUBARCHE (ADRENARCHE)

Premature adrenarche has traditionally applied to the appearance of sexual hair before the age of 8 yr in girls or 9 yr in boys without other evidence of maturation. It is much more frequent in girls than in boys. The higher prevalence of this condition in African-American and, to a smaller extent, Latino girls in comparison to white girls may suggest that the cutoff age for the definition of “premature” should be adjusted for different ethnic groups on the basis of epidemiologic data. Hair appears on the mons and labia majora in girls and perineal and scrotal area in boys; axillary hair generally appears later. Adult-type axillary odor is common. Affected children are often slightly advanced in height and osseous maturation. Premature adrenarche is an early maturational event of adrenal androgen production. This event coincides with precocious maturation of the zona reticularis, an associated decrease in 3β-hydroxysteroid dehydrogenase activity, and an increase in C-17,20-lyase activity. These enzymatic changes result in increased basal and ACTH-stimulated serum concentrations of the Δ'-steroids (17α-hydroxyprogrenolone and dehydroepiandrosterone) and, to a lesser extent, of the Δ'-steroids (particularly androstenedione) compared with age-matched control subjects. The levels of these steroids and of dehydroepiandrosterone sulfate are usually comparable to those of older children in the early stages of normal puberty. Idiopathic premature adrenarche is a slowly progressive condition that requires no therapy. However, a subset of patients with precocious pubarche has 1 or more features of systemic androgen effect, such as marked growth acceleration, clitoral (girls) or phallic (boys) enlargement, cystic acne, or advanced bone age (>2 SD above the mean for age). In these patients with atypical premature adrenarche, an ACTH stimulation test with measurement of steroid intermediates (mainly, serum 17α-hydroxyprogesterone concentrations) is indicated to rule out nonclassical congenital adrenal hyperplasia caused by 21-hydroxylase deficiency. Epidemiologic and molecular genetic studies show that the prevalence of nonclassical 21-hydroxylase deficiency is approximately 3-6% of unselected children with precocious pubarche; the prevalence of other enzyme defects (i.e., 3β-hydroxysteroid dehydrogenase or 11β-hydroxylase deficiency) is extremely low. Although idiopathic premature adrenarche has been considered a benign condition, longitudinal observations suggest that approximately 50% of girls with premature adrenarche are at high risk for hyperandrogenism and polycystic ovary syndrome, alone or more often in combination with other components of the so-called metabolic syndrome (insulin resistance possibly progressing to type 2 diabetes mellitus, dyslipidemia, hyper tension, increased abdominal fat) as adults. Whether the unfavorable progression to pubertal hyperandrogenism can be prevented by insulin-sensitizing agents (metformin 850-1,000 mg/day) or lifestyle interventions (diet, exercise) remains to be proven in large studies. An increased risk of premature adrenarche and the metabolic syndrome is documented in children born small for their gestational age. This appears to be associated with insulin resistance and decreased β-cell reserve, perhaps as a consequence of fetal undernutrition.

PREMATURE MENARCHE

This is a rare entity, much less frequent than premature thelarche or premature adrenarche, and is a diagnosis of exclusion. In girls with isolated vaginal bleeding in the absence of other secondary sexual characteristics, more common causes, such as vulvovaginitis, a foreign body (typically associated with malodororous discharge), or sexual abuse, and uncommon causes, such as urethral prolapse and sarcoma botryoides, must be carefully excluded. The majority of girls with idiopathic premature menarche have only 1-3 episodes of bleeding; puberty occurs at the usual time, and menstrual cycles are normal. Plasma levels of gonadotropins are low, but estradiol levels may be occasionally elevated, probably owing to episodic ovarian estrogen secretion associated with ovarian follicular cysts that can be detected on ultrasound.

562.9 Medicational Precocity

Luigi R. Garibaldi and Wassim Chemaitilly

A variety of medications can induce the appearance of secondary sexual characteristics that may be confused with precocious puberty. A careful history focused on exploring the possibility of accidental exposure to, or ingestion of, sex hormones is important. Peripheral precocious puberty has occurred in boys and girls from the accidental ingestion of estrogens (including contraceptive pills) and from the administration of anabolic steroids. The most common cause of medicational precocity is currently related to the widespread use of testosterone gels or creams that are applied to the skin for treatment of male hypogonadism. This has resulted in virilization of children and women following skin contact at, and systemic absorption from, the area where the gel/cream was applied by their family member.

Less commonly, estrogens in cosmetics, hair creams, and breast augmentation creams have caused breast development in girls and gynecomastia in boys, via percutaneous absorption. The high prevalence of premature thelarche and peripheral precocious puberty in Puerto Rico has been attributed to contamination of meats, particularly chicken, with estrogens used in animal husbandry, but has not been proved. Exogenous estrogens may produce a darkening of the areola that is not usually seen in endogenous types of precocity. The precocious changes disappear after cessation of exposure to the hormones.

Disorders of the Thyroid Gland

Chapter 563
Thyroid Development and Physiology
Stephen H. LaFranchi and Stephen A. Huang

FETAL DEVELOPMENT
The fetal thyroid arises from an outpouching of the foregut at the base of the tongue (foramen cecum). It migrates to its normal location over the thyroid cartilage by 8-10 wk of gestation. The thyroid bilobed shape is recognized by 7 wk of gestation, and characteristic thyroid follicle cell and colloid formation is seen by 10 wk. Thyroglobulin synthesis occurs from 4 wk, iodine trapping occurs by 8-10 wk, and thyroxine (T_4) and, to a lesser extent, triiodothyronine (T_3) synthesis and secretion occur from 12 wk of gestation. There is evidence that several transcription factors—TTF-1/NKX-2.1, TTF-2 (also termed FOXE1), NKX2.5, and PAX8—are important in thyroid gland morphogenesis and differentiation, and possibly also in its caudal migration to its final location. These factors also bind to the promoters of thyroglobulin and thyroid peroxidase genes and so influence thyroid hormone production. Hypothalamic neurons synthesize thyrotropin—releasing hormone (TRH) by 6-8 wk, the pituitary portal vessel system begins development by 8-10 wk, and thyroid-stimulating hormone (TSH) secretion is evident by 12 wk of gestation. Maturation of the hypothalamic-pituitary-thyroid axis occurs over the second half of gestation, but normal feedback relationships are not mature until approximately 3 mo of postnatal life. Other transcription factors, including PROP-1 and Pit-1, are important for differentiation and growth of thyrotrphs, along with somatotrophs and lactotrophs.

THYROID PHYSIOLOGY
The main function of the thyroid gland is to synthesize T_4 and T_3. The only known physiologic role of iodide (or iodine [I]) in its ionized form is in the synthesis of these hormones; the recommended dietary allowance of iodine is 30 µg/kg/24 hr for infants, 90-120 µg/kg/24 hr for children, and 150 µg/kg/24 hr for adolescents and adults.

The median iodine intake in the United States decreased by approximately 50% between the 1970s (320 µg/L) and the 1990s (145 µg/L), but it now appears to have stabilized (2009-2010 = 144 µg/L). Whatever the chemical form ingested, iodine eventually reaches the thyroid gland as iodide. Thyroid tissue has an avidity for iodide and is able to trap (with a gradient of 100:1), transport, and concentrate it in the follicular lumen for synthesis of thyroid hormone. Entry of iodide from the circulation into the thyroid is carried out by the sodium–iodide symporter. Iodide diffuses across the cell to the apical membrane where it is transported into the colloid via pendrin.

Before trapped iodide can react with tyrosine, it must be oxidized; this reaction is catalyzed by thyroid peroxidase. Dual oxidase maturation factor 2 (DUOXA2) is required to express DUOX2 enzymatic activity, which is required for H_2O_2 generation, a crucial step in iodide oxidation. The thyroid cells produce thyroglobulin, a large globular glycoprotein with a molecular weight of approximately 660,000, containing approximately 120 tyrosine units. Iodination of tyrosine forms monoiiodotyrosine and diiodotyrosine; 2 molecules of diiodotyrosine then couple to form 1 molecule of T_4, or 1 molecule of diiodothyrosine and 1 of monoiiodotyrosine to form T_3. Once formed, hormones are stored as thyroglobulin in the lumen of the follicle (colloid) until ready to be delivered to the body cells. T_4 and T_3 are liberated from thyroglobulin by activation of proteases and peptidases.

The metabolic potency of T_3 is 3-4 times that of T_4. In adults, the thyroid produces approximately 100 µg of T_4 and 20 µg of T_3 daily. Only 20% of circulating T_4 is secreted by the thyroid; the remainder is produced by deiodination of T_3 in the liver, kidney, and other extrathyroid tissues by type I 5'-deiodinase. Selenocysteine is the active center of the iodothyronine deiodinases. Thus, selenium indirectly plays a role in normal growth and development. In the pituitary and brain, approximately 80% of required T_4 is produced locally from T_3 by a different enzyme, type II 5'-deiodinase. The level of T_3 in blood is one fiftieth that of T_4, but T_3 is the physiologically active thyroid hormone.

Thyroid hormones increase oxygen consumption, stimulate protein synthesis, influence growth and differentiation, and affect carbohydrate, lipid, and vitamin metabolism. Specific thyroid hormone transporters, of which the most important is monocarboxylate transporter 8, facilitate entry of T_4 and T_3 into cells. Once into the cell, T_4 is converted to T_3 by type I or II 5'-deiodinase. Intracellular T_3 then enters the nucleus, where it binds to thyroid hormone receptors. Thyroid hormone receptors are members of the steroid hormone receptor superfamily that includes glucocorticoids, estrogen, progestrone, vitamin D, and retinoids. Four different isoforms of the thyroid hormone receptor (α, α', β, and β') are expressed in different tissues; the protein product of the formerly designated c-erb A protooncogene (THRA2) is the α hormone receptor in the brain and hypothalamic. Thyroid hormone receptors consist of a ligand-binding domain (binds T_3), hinge region, and DNA-binding domain (zinc finger). Binding of T_3 activates the thyroid hormone receptor response element, resulting in production of an encoded messenger RNA and protein synthesis specific for the target cell. In this manner, a single hormone, T_4, acting through tissue-specific thyroid hormone receptor isoforms and gene-specific thyroid response elements, can produce multiple effects in various tissues.

Approximately 70% of the circulating T_4 is firmly bound to T_3-binding globulin (TBG). Less-important carriers are T_4-binding prealbumin, called transthyretin, and albumin. Only 0.03% of T_3 in serum is not bound and comprises free T_3. Approximately 50% of circulating T_3 is bound to TBG, and 50% is bound to albumin; 0.30% of T_3 is unbound, or free, T_3. Because the concentration of TBG is altered in many clinical circumstances, its status must be considered when interpreting total T_3 or T_4 levels.

THYROID REGULATION
The thyroid is regulated by TSH, a glycoprotein produced and secreted by the anterior pituitary. This hormone stimulates adenylate cyclase in the thyroid and causes the release of T_4 and T_3. Thyroid hormones increase oxygen consumption, influence growth and differentiation, and affect carbohydrate, lipid, and vitamin metabolism. Specific thyroid hormone transporters, of which the most important is monocarboxylate transporter 8, facilitate entry of T_4 and T_3 into cells. Once into the cell, T_4 is converted to T_3 by type I or II 5'-deiodinase. Intracellular T_3 then enters the nucleus, where it binds to thyroid hormone receptors. Thyroid hormone receptors are members of the steroid hormone receptor superfamily that includes glucocorticoids, estrogen, progestrone, vitamin D, and retinoids. Four different isoforms of the thyroid hormone receptor (α, α', β, and β') are expressed in different tissues; the protein product of the formerly designated c-erb A protooncogene (THRA2) is the α hormone receptor in the brain and hypothalamic. Thyroid hormone receptors consist of a ligand-binding domain (binds T_3), hinge region, and DNA-binding domain (zinc finger). Binding of T_3 activates the thyroid hormone receptor response element, resulting in production of an encoded messenger RNA and protein synthesis specific for the target cell. In this manner, a single hormone, T_4, acting through tissue-specific thyroid hormone receptor isoforms and gene-specific thyroid response elements, can produce multiple effects in various tissues.
T₄ and TSH may remain normal. The decreased levels of T₃ may be a physiologic adaptation, resulting in decreased rates of oxygen production, of substrate use, and of other catabolic processes.

563.1 Thyroid Hormone Studies

Stephen H. LaFranchi

SERUM THYROID HORMONES
Methods are available to measure all the thyroid hormones in serum: T₄, free T₄, T₃, and free T₃. Metabolically inert T₃ (3,5,3’-triiodothyronine), called reverse T₃, is also present in serum. Age must be considered in interpreting results, particularly in the neonate.

Thyroglobulin is a glycoprotein that is secreted through the apical surface of the thyroid follicular cell into the colloid. Small amounts escape into the circulation and are measurable in serum. Levels increase with TSH (also called thyrotropin) stimulation and decrease with TSH suppression. Serum thyroglobulin levels are increased in the neonate, in patients with Graves disease and other forms of autoimmune thyroid disease, and in those with endemic goiter. The most marked elevations of thyroglobulin occur in patients with differentiated carcinoma of the thyroid. Athyreotic infants have markedly reduced levels of thyroglobulin in serum.

Serum TSH levels are the most accurate test of thyroid function. Serum TSH levels are elevated in primary hypothyroidism and suppressed in hyperthyroidism. After the neonatal period, normal levels of TSH are <6 mIU/L. With central (secondary) hypothyroidism, serum TSH may be subnormal, though often it is “inappropriately” in the normal range, despite a low serum T₄ or free T₄ level. TSH appears to be less biologically active in central hypothyroidism. These sensitive (third-generation) TSH assays obviate the need for TRH stimulation in the diagnosis of most patients with thyroid disorders.

FETAL AND NEWBORN THYROID
Fetal serum T₄ and free T₄ increase progressively from midgestation to approximately 11.5 µg/dL and 1.5 ng/dL, respectively, at term. Fetal levels of T₃ are low before 20 wk and then gradually increase to approximately 45 ng/dL at term. Reverse T₃ levels (inactive form of T₃), however, are high in the fetus (250 ng/dL at 30 wk) and decrease to 150 ng/dL at term. Serum levels of TSH gradually increase to 10 mU/L at term. Approximately one third of maternal T₄ crosses the placenta to the fetus. Maternal T₄ plays a role in fetal development, especially that of the brain, before the synthesis of fetal thyroid hormone begins. The fetus of a hypothyroid mother may be at risk for neurologic injury, and a hypothyroid fetus may be partially protected by maternal T₄ until delivery. The amount of T₄ that crosses the placenta is not sufficient to interfere with a diagnosis of congenital hypothyroidism in the neonate.

At birth, there is an acute release of TSH; peak serum concentrations reach 60 mU/L 30 min following delivery in full-term infants. A rapid decline occurs in the ensuing 24 hr and a more gradual decline over the next 5 days to <10 mU/L. The acute increase in TSH produces a dramatic increase in levels of T₄ to approximately 16 µg/dL and of T₃ to approximately 300 ng/dL in about 4 hr. This T₄ seems largely derived from increased peripheral conversion of T₄ to T₃, T₃ levels gradually decrease during the first 2 wk of life to 12 µg/dL. T₃ levels decline during the 1st wk of life to levels below 200 ng/mL. Serum free T₃ levels are 0.9–2.3 ng/dL in infancy and decline to 0.7–1.8 ng/dL in childhood. Serum free T₄ concentrations are approximately 180–760 pg/dL in infancy and decline to 230–650 pg/dL in childhood. Reverse T₃ levels are maintained for 2 wk (200 ng/dL) and decrease by 4 wk to around 50 ng/dL. In preterm infants, changes in thyroid function after birth are qualitatively similar to but quantitatively smaller than in full-term infants. Serum T₄ and T₃ levels are decreased in proportion to gestational age and birthweight.

SERUM THYROXINE-BINDING GLOBULIN
The thyroid hormones are transported in plasma bound to TBG, a glycoprotein synthesized in the liver. Estimation of TBG levels is occasionally necessary because TBG is increased or decreased in a variety of clinical situations, with effects on the level of total T₄ and T₃. TBG binds approximately 70% of T₄, and 50% of T₃. TBG levels increase in pregnancy, in the newborn period, with hepatitis, and with administration of estrogens (oral contraceptives), selective estrogen receptor modulators, heroin or methadone, mitotane, 5-fluorouracil, and phenobarbital, and they decrease with androgens, anabolic steroids, glucocorticoids, nicotinic acid, and l-asparaginase. These effects are the results of modulation of hepatic synthesis of TBG. TBG levels may be markedly decreased owing to decreased production with hepatocellular disease or loss of the gut with protein-losing enteropathies or in urine, as in the congenital nephrotic syndrome. Decreased or increased levels of TBG also occur as genetic traits (see Chapter 564).

Some drugs, in particular phenytoin, carbamazepine, furosemide, salicylates, nonsteroidal antiinflammatory drugs, and heparin, also inhibit binding of T₄ and T₃ to TBG. In addition, phenytoin and carbamazepine cause abnormalities of thyroid function tests by another mechanism. They stimulate hepatic cytochrome P450 degradation of T₄ and accelerate transport of T3 into tissues.

IN VIVO RADIONUCLIDE STUDIES
Markedly improved direct tests of thyroid function have made radioactive iodine uptake studies less necessary. The iodine trapping or concentrating mechanism of the thyroid can be evaluated by measuring the uptake of radioactive isotope ¹³¹I (half-life: 13 hr). The technology allows doses of radioiodine (0.1–0.5 mCi) that are only a fraction of those used with ¹³¹I. Technetium (¹⁹⁹mTc) is a particularly useful radioisotope for children because in contrast to iodine, it is trapped but not organified by the thyroid and has a half-life of only 6 hr. Thyroid scanning may be indicated to assess the presence of thyroid tissue in questions of thyroid dysgenesis and to detect ectopic thyroid tissue, and thyroid uptake may be indicated to evaluate possible “hot” thyroid nodules. Diagnostic studies should be performed with ¹³¹I and ¹⁹⁹mTc pertechnetate or ¹²³I because they have the advantages of lower radiation exposure and high-quality scintigrams. Radioiodine treatment, which may be used to treat children with Graves hyperthyroidism or differentiated thyroid cancer, employs administration of ¹³¹I, which has a longer half-life (8 days) and greater killing effect.

THYROID ULTRASONOGRAPHIC STUDIES
Thyroid ultrasound examinations can determine the location, size, and shape of the thyroid gland, and they are useful for assessing the solid or cystic nature of nodules. Ultrasound is not as reliable as radionuclide studies in evaluating infants with suspected thyroid dysgenesis, particularly ectopic glands. Ultrasound examinations are useful in identifying normal thyroid gland position in children with suspected thyroglossal duct cysts. In children with autoimmune thyroiditis, ultrasound reveals scattered hypoechoogenicity. Ultrasound examinations are more accurate than physical examination in estimating goiter size and assessing thyroid nodules. Certain characteristics of thyroid nodules, such as blurred margins, microcalcifications, hypoechoogenicity, taller-than-wide shape,capsular extension, and increased vascularity, increase the likelihood of thyroid cancer, although none of these features is 100% sensitive or specific.

Bibliography

Abnormalities in levels of thyroxine-binding globulin (TBG) are not associated with clinical disease and do not require treatment. They are usually uncovered by a chance finding of abnormally low or high levels of thyroxine (T₄) and may be a source of confusion in the diagnosis of hypothyroidism or hyperthyroidism.

TBG deficiency occurs as an X-linked dominant disorder. Congenital TBG deficiency is most often discovered through screening programs for neonatal hypothyroidism that measure levels of T₄ as the primary screening test. Affected patients have low levels of total T₄ and elevated resin triiodothyronine uptake, but levels of free T₄ and thyroid-stimulating hormone are normal. The diagnosis is confirmed by the finding of absent or low levels of TBG. TBG deficiency occurs in 1 in 2,400 male newborns, 36% of whom have TBG levels <1 mg/dL. Milder forms of TBG deficiency occur in approximately 1 in 42,000 heterozygous female newborns. Complete TBG deficiency (<5 µg/dL) occurs much less often. To date, more than 25 different mutations have been reported in the TBG gene, resulting in either decreased TBG levels or reduced affinity of TBG for T₄. Table 564-1 lists causes of acquired TBG deficiency.

TBG excess also is a harmless X-linked dominant anomaly, occurring in approximately 1 in 25,000 persons. It has been recognized primarily in adults, but newborn screening programs may uncover the condition in the neonate. The level of T₄ is elevated, triiodothyronine is variably elevated, thyroid-stimulating hormone and free T₄ are normal, and resin triiodothyronine uptake is decreased. The elevated levels of TBG confirm the diagnosis. In affected neonates, levels of T₄ as high as 95 µg/dL have been found, which decrease to 20-30 µg/dL after 2-3 wk. Such high levels of T₄ may be related in part to the normally elevated levels of TBG in neonates, presumably as an effect of maternal estrogens. Affected patients are euthyroid. Family studies may be indicated to alert other affected family members. Table 564-1 lists causes of acquired TBG excess.

Familial dysalbuminemic hyperthyroxinemia is an autosomal dominant disorder that may be confused with hyperthyroidism. Markedly increased binding of T₄ to an abnormal albumin variant leads to increased serum concentrations of T₄. However, the levels of free T₃, free triiodothyronine, and thyroid-stimulating hormone are normal.

Levels of triiodothyronine are normal or only slightly elevated. Affected patients are euthyroid.

Benvenga S: Thyroid hormone transport proteins and the physiology of hormone binding. In Braverman LE, Cooper DS, editors: Werner & Ingbar's the thyroid: a fundamental and clinical text, ed 10, Philadelphia, 2013, Lippincott Williams & Wilkins, pp 93–102.

Hypothyroidism results from deficient production of thyroid hormone, either from a defect in the gland itself (primary hypothyroidism) or a result of reduced thyroid-stimulating hormone (TSH) stimulation (central or hypopituitary hypothyroidism; Table 565-1). The disorder may be manifested from birth (congenital) or acquired. When symptoms appear after a period of apparently normal thyroid function, the disorder may be truly acquired or might only appear so as a result of one of a variety of congenital defects in which the manifestation of the deficiency is delayed.

**CONGENITAL HYPOTHYROIDISM**
Most cases of congenital hypothyroidism are not hereditary and result from thyroid dysgenesis. Some cases are familial; these are usually caused by one of the inborn errors of thyroid hormone synthesis (dys-hormonogenesis) and may be associated with a goiter. Most infants with congenital hypothyroidism are detected by newborn screening programs in the 1st few wk after birth, before obvious clinical symptoms and signs develop. In infants born in areas with no screening program, severe cases manifest features in the 1st few wk of life, but in cases of milder deficiency, manifestations may be delayed for months.

**Epidemiology**
The prevalence of congenital hypothyroidism based on nationwide programs for neonatal screening was initially reported at 1 in 4,000 infants worldwide. Over the last 2 decades, the prevalence has dropped to 1 in 2,000, likely the result of detection of milder cases of hypothyroidism. Studies from the United States report that the prevalence is lower in black Americans and higher in Asian-Americans and Pacific Islanders, Hispanics, and Native Americans as compared to white babies.

**Etiology**
See Table 565-1.

**Primary Hypothyroidism**

**Thyroid Dysgenesis.** Some form of thyroid dysgenesis (aplasia, hypoplasia, or an ectopic gland) is the most common cause of permanent congenital hypothyroidism, accounting for 80-85% of cases. In approximately 33% of cases of dysgenesis, even sensitive radionuclide scans can find no remnants of thyroid tissue (aplasia). In the other 66% of infants, rudiments of thyroid tissue are found in an ectopic location, anywhere from the base of the tongue (lingual thyroid) to the normal position in the neck (hypoplasia). Thyroid dysgenesis has a 2:1 female: male ratio.

The cause of thyroid dysgenesis is unknown in most cases. Thyroid dysgenesis occurs sporadically, but familial cases occasionally have been reported. The finding that thyroid developmental anomalies, such as thyroglossal duct cysts and hemiagenesis, are present in 8-10% of 1st-degree relatives of infants with thyroid dysgenesis supports an underlying genetic component.

Mutations in several transcription factors important for thyroid morphogenesis and differentiation (including TTF-1/NKX2.1, TTF-2 [also termed FOXE1], and PAX8) are monogenic causes of approximately 2% of the cases of thyroid dysgenesis. In addition, genetic
Defects leading to absent or ineffective thyrotropin (TSH) receptor binding or signaling have been described. The transcription factor TTF-1/NKX2.1 is expressed in the thyroid, lung, and central nervous system. Mutations in TTF-1/NKX2.1 are reported to result in congenital hypothyroidism, respiratory distress, and persistent neurologic problems, including chorea and ataxia, despite early thyroid hormone treatment. NKX2.5 is expressed in the thyroid and heart. Mutations in NKX2.5 are associated with congenital hypothyroidism and cardiac malformations. PAX-8 is expressed in the thyroid and kidney. Mutations in PAX-8 are associated with congenital hypothyroidism and kidney and ureteral malformations.

The common finding of thyroid dysgenesis confined to only 1 of a pair of monozygotic twins suggests the operation of a deleterious factor during intrauterine life. Maternal antithyroid antibodies might be that factor. Although thyroid peroxidase antibodies have been detected in some mother–infant pairs, there is little evidence of their pathogenicity. The demonstration of thyroid growth-blocking and cytotoxic antibodies in some infants with thyroid dysgenesis, as well as in their mothers, suggests a more likely pathogenetic mechanism.

**Defective Synthesis of Thyroxine (Dyshormonogenesis).** A variety of defects in the biosynthesis of thyroid hormone can result in congenital hypothyroidism; these account for 15% of cases detected by neonatal screening programs (1 in 30,000–50,000 live births). These defects are transmitted in an autosomal recessive manner. A goiter is almost always present. When the defect is incomplete, compensation occurs, and onset of hypothyroidism may be delayed for years.

**Defect of Iodide Transport.** Defect of iodide transport is rare and involves mutations in the sodium–iodide symporter. Among the several cases now reported, it has been found in 9 related infants of the Hutterite sect, and approximately 50% of the cases are from Japan. Consanguinity is a factor in approximately 30% of the families.

In the past, clinical hypothyroidism, with or without a goiter, often developed in the 1st few months of life; the condition has been detected in neonatal screening programs. In Japan, however, untreated patients acquire goiter and hypothyroidism after 10 yr of age, perhaps because of the very high iodine content (often 19 mg/24 hr) of the Japanese diet.

The energy-dependent mechanisms for concentrating iodide are defective in the thyroid and salivary glands. In contrast to other defects of thyroid hormone synthesis, uptake of radioiodine and pertechnetate is low; a reduced saliva:serum ratio of 123I will support the diagnosis, confirmed by finding a mutation in the sodium–iodide symporter gene. This condition responds to treatment with large doses of potassium iodide, but treatment with l-thyroxine is preferable.

**Thyroid Peroxidase Defects of Organization and Coupling.** Thyroid peroxidase defects of organization and coupling are the most common of the thyroid (T_4) synthetic defects. After iodide is trapped by the thyroid, it is rapidly oxidized to reactive iodine, which is then incorporated into tyrosine units on thyroglobulin. This process requires generation of H_2O_2, thyroid peroxidase, and hematin (an enzyme cofactor); defects can involve each of these components, and there is considerable clinical and biochemical heterogeneity. In the Dutch neonatal screening program, 23 infants were found with a complete organization defect (1 in 60,000 live births), but its prevalence in other areas is unknown. A characteristic finding in all patients with this defect is a marked “discharge” of thyroid radioactivity when perchlorate or thiocyanate is administered 2 hr after administration of a test dose of radioiodine. In these patients, perchlorate discharges 40-90% of radioiodine compared with <10% in normal persons. Several mutations in the thyroid peroxidase gene have been reported in children with congenital hypothyroidism.

Dual oxidase maturation factor 2 (DUOX2) is required to express DUOX2 enzymatic activity, which is required for H_2O_2 generation, a crucial step in iodide oxidation. Biallelic DUOX2 mutations produce permanent congenital hypothyroidism, whereas monoallelic mutations are associated with transient hypothyroidism. DUOX2 mutations can also cause permanent or transient congenital hypothyroidism. DUOX2 mutations are relatively common, present in 30% of cases of apparent dyshormonogenesis, whereas DUOX2 mutations are relatively rare, present in 2% of such cases.

**Pendred syndrome** is an autosomal recessive disorder caused by a mutation in the chloride–iodide transport protein common to the thyroid gland and the cochlea. Pendred syndrome is comprised of sensorineural deafness and goiter; it is the most common cause of syndromic deafness. Pendrin allows transport of iodide from the follicular cell into the colloid where it undergoes organification to iodine and incorporation into the tyrosine residues on thyroglobulin. Patients with a mutation in the pendrin gene have impaired iodide organification and a positive perchlorate discharge.

**Defects of Thyroglobulin Synthesis.** Defects of thyroglobulin synthesis are a heterogeneous group of disorders characterized by goiter, elevated serum TSH, low T_4_ levels, and absent or low levels of thyroglobulin. It has been reported in approximately 100 patients. Molecular defects, primarily point mutations, have been described in several patients.

Isolated TRH deficiency: mutation in TRH gene

TRH unresponsiveness: mutation in TRH receptor gene

Multiple congenital pituitary hormone deficiencies (e.g., septooptic dysplasia)

PIT-1 mutations

• Deficiency of TSH
• Deficiency of growth hormone
• Deficiency of prolactin

PROP-1 mutations

• Deficiency of TSH
• Deficiency of growth hormone
• Deficiency of prolactin

• Deficiency of LH
• Deficiency of FSH
• Deficiency of ACTH

ACTH, adrenocorticotrophic hormone; FSH, follicle-stimulating hormone; LH, luteinizing hormone; TRH, thyroid-releasing hormone; TSH, thyroid-stimulating hormone.
Defects in Deiodinase. Monoiodotyrosine and diiodotyrosine released from thyroglobulin are normally deiodinated within the thyroid or in peripheral tissues by a deiodinase. The liberated iodine is recycled in the synthesis of thyroid hormones. The DEHAL gene encodes iodotyrosine deiodinase in the thyroid. DEHAL1 mutations are relatively rare; patients with deiodinase deficiency experience severe iodine loss from the constant urinary excretion of nondeiodinated tyrosines, leading to hormonal deficiency and goiter. The deiodination defect may be limited to thyroid tissue only or to peripheral tissue only, or it may be universal.

Thyrotropin Hormone Unresponsiveness. A mutation in the TSH receptor gene is a relatively uncommon autosomal recessive cause of congenital hypothyroidism. Both homozygous and compound heterozygous mutations in the TSH receptor gene have been reported. The failed TSH receptor requires T4 or T3, free T4, and free T3 to be elevated. These findings often have led to the erroneous diagnosis of Graves disease, although most affected patients are clinically euthyroid. The unresponsiveness can vary among tissues. There may be subtle clinical features of hypothyroidism, including developmental delay, growth retardation, and delayed skeletal maturation. On the other hand, there may be clinical features compatible with hyperthyroidism, such as tachycardia and hyperreflexia. It is presumed that these patients have varying tissue resistance to thyroid hormone. One neurologic manifestation is an increased association of attention-deficit/hyperactivity disorder; the converse is not true because patients with attention-deficit/hyperactivity disorder do not have an increased risk of thyroid hormone resistance.

TSH levels are diagnostic in that they are not suppressed as in Graves disease but instead are moderately elevated or normal but inappropriate for the levels of T4, T3, and free T4. The failure of TSH suppression indicates that the resistance is generalized and affects the pituitary gland as well as peripheral tissues. More than 40 distinct point mutations in the hormone-binding domain of the β-thyroid receptor are identified. Different phenotypes do not correlate with genotypes. The same mutation has been observed in patients with generalized or isolated pituitary resistance, even in different members of the same family. A child homozygous for the receptor mutation showed unusually severe resistance. These cases support the dominant negative effect of mutant receptors, in which the mutant receptor protein inhibits normal receptor action in heterozygotes. Elevated levels of TSH on neonatal thyroid screening should suggest the possibility of this diagnosis. No treatment is usually required unless growth and skeletal retardation are present.

Two infants of consanguineous matings are known to have an autosomal recessive form of thyroid resistance. These infants had manifestations of hypothyroidism early in life, and genetic studies revealed a major deletion of the β-thyroid receptor in 1 of them. The resistance appears to be more severe in this form of the entity.

Some patients have greater resistance to thyroid hormone in the pituitary gland as compared to peripheral tissues. Because the peripheral tissues are not resistant to thyroid hormones, the patient has a goiter and manifestations of hyperthyroidism. The laboratory findings are the same as those of Graves disease, with generalized thyroid hormone resistance. This condition must be differentiated from a pituitary TSH-secreting tumor. Different treatments, including d-thyroxine, triiodothyroacetic acid, and tetraiodothyroacetic acid, have been successful in some patients. Bromocriptine administration, which interferes with TSH secretion, was reported to be successful in another patient. Whether isolated pituitary resistance to thyroid hormone exists as a distinct entity is controversial; it may be a variant of generalized resistance to thyroid hormone with varying tissue responsiveness.

Although the majority of patients with resistance have mutations in the thyroid hormone receptor β gene, a child with a mutation in the thyroid hormone receptor α gene has been reported. This patient presented at age 6 yr with growth retardation, delayed development, and constipation. Genetic analysis showed a heterozygous nonsense mutation in the thyroid hormone receptor α gene that, like β gene mutations, inhibited wild-type receptor action in a dominant negative manner.

Thyrotropin Receptor-Blocking Antibody. Maternal TRAB inhibits binding of TSH to its receptor in the neonate. Maternal TRAB accounts for 2% of cases detected by neonatal screening programs (1 in 50,000-100,000 infants). It should be suspected whenever there is a history of maternal autoimmune thyroid disease, including Hashimoto thyroiditis or Graves disease, maternal hypothyroidism on replacement therapy, or recurrent congenital hypothyroidism of a transient nature in previous siblings. In these situations, maternal levels of TRAB (measured as thyrotropin-binding inhibitor immunoglobulin) should be determined during pregnancy. Affected infants and their mothers also can have thyrotropin receptor–stimulating antibodies and thyroid peroxidase antibodies. Technetium pertechnetate and 131I scans might fail to detect any thyroid tissue, mimicking thyroid agenesis, but ultrasonography will show a thyroid gland. After the condition remits, a normal thyroid gland is demonstrable by scanning following discontinuation of replacement therapy. The half-life of the antibody is 21 days, and remission of the hypothyroidism occurs in approximately 3-6 mo. Correct diagnosis of this cause of congenital hypothyroidism prevents unnecessary protracted treatment, alerts the clinician to possible recurrences in future pregnancies, and allows a favorable prognosis.

Radioiodine Administration. Hypothyroidism can occur as a result of inadvertent administration of radioiodine during pregnancy for treatment of Graves disease or cancer of the thyroid. The fetal thyroid is capable of trapping iodide by 70-75 days of gestation. Whenever radioiodine is administered to a woman of childbearing age, a pregnancy test must be performed before a therapeutic dose of 131I is given, regardless of the menstrual history or putative history of contraception. Administration of radioactive iodine to lactating women also is contraindicated because it is readily excreted in milk.

Iodine Exposure. Congenital hypothyroidism can result from fetal exposure to excessive iodides. Perinatal exposure can occur with the use of iodine antiseptic to prepare the skin for caesarian section or painting of the cervix before delivery. It has also been reported in infants born to mothers who consumed large amounts of iodine daily (up to 12 mg) in the form of nutritional supplements and in mothers in Japan who consumed large quantities of iodine-rich seaweed. These conditions are transitory and must not be mistaken for the other forms of hypothyroidism. In the neonate, topical iodine-containing antiseptics used in nurseries and by surgeons can also cause transient congenital hypothyroidism, especially in low-birthweight infants, and can...
lead to abnormal results on neonatal screening tests. In older children, the usual sources of iodides are proprietary preparations used to treat asthma. In a few instances, the cause of hypothyroidism was amiodarone, an antiarrhythmic drug with high iodine content. In most of these instances, goiter is present (see Chapter 567).

**Iodine-Deficiency Endemic Goiter.** See Chapter 567.3. Iodine deficiency or endemic goiter is the most common cause of congenital hypothyroidism worldwide. The recommended intake of iodine in adults is 150 μg daily, increasing to 250 μg daily during pregnancy to allow for fetal iodine requirements. Despite efforts at universal iodization of salt in many countries, economic, political, and practical obstacles make achieving this objective difficult. While the U.S. population is iodine-sufficient as a whole, approximately 15% of women of reproductive age fall into the iodine-deficient category. Borderline iodine deficiency is more likely to cause problems in preterm infants who depend on a maternal source of iodine for normal thyroid hormone production.

**Central (Hypopituitary) Hypothyroidism**

**Thyrotropin and Thyrotropin-Releasing Hormone Deficiency.** Deficiency of TSH and central hypothyroidism can occur in any of the conditions associated with developmental defects of the pituitary or hypothalamus (see Chapter 557). More often in these conditions, the deficiency of TSH is secondary to a deficiency of thyrotropin-releasing hormone (TRH). TSH-deficient hypothyroidism is found in 1 in 30,000–50,000 infants; most screening programs are designed to detect primary hypothyroidism, so most of these cases are not detected by neonatal thyroid screening. The majority of affected infants have multiple pituitary deficiencies and present with hypoglycemia, persistent jaundice, and micrognathia in association with septo-optic dysplasia, midline cleft lip, midface hypoplasia, and other midline facial anomalies.

Mutations in genes coding for transcription factors essential to pituitary development, cell type differentiation, and hormone synthesis are associated with congenital TSH deficiency. **PIT-1** mutations include TSH deficiency associated with growth hormone and prolactin deficiency. Patients with **PROP-1** mutations (“prophet of pit-1”) have not only TSH, growth hormone, and prolactin deficiency but also luteinizing hormone and follicle-stimulating hormone deficiency and variable adrenocorticotropic hormone deficiency. **HESX1** mutations are associated with TSH, growth hormone, prolactin, and adrenocorticotropic hormone deficiencies and are found in some patients with optic nerve hypoplasia (septo-optic dysplasia syndrome; see Chapter 591).

Isolated deficiency of TSH is a rare autosomal recessive disorder that has been reported in several sibships. DNA studies in affected family members reveal defects in the TSH β-subunit gene, including point mutations, frame shifts causing a stop codon, and splice-site mutations. Depending on the specific mutation, serum TSH levels may be undetectable, measurable, or elevated. The diagnosis is usually delayed because the serum TSH level is not elevated in most cases, and so such patients are not detected by newborn screening programs.

**Thyrotropin-Releasing Hormone Receptor Abnormality.** Mutations in the THR receptor gene, a rare cause of congenital central hypothyroidism, have now been reported in a few families. This condition, which results in isolated TSH deficiency and hypothyroidism, was suspected because of failure of both TSH and prolactin to respond to TRH stimulation.

**Thyroid Function in Preterm Babies**

Postnatal thyroid function in preterm babies is qualitatively similar but quantitatively reduced compared with that of term infants. The cord serum T₄ is decreased in proportion to gestational age and birthweight. The postnatal TSH surge is reduced, and the more premature, very-low-birthweight infants with complications of prematurity, such as respiratory distress syndrome, actually experience a decrease in serum T₄ in the 1st wk of life. As these complications resolve, the serum T₄ gradually increases so that generally by 6 wk of life it enters the T₄ range seen in term infants. Serum free T₄ concentrations seem less affected, and when measured by equilibrium dialysis, these levels are often normal. Preterm babies also have a higher incidence of “delayed” TSH elevation and apparent transient primary hypothyroidism. Premature infants of <28 wk of gestation might have problems resulting from a combination of immaturity of the hypothalamic-pituitary-thyroid axis and loss of the maternal contribution of thyroid hormone and so may be candidates for temporary thyroid hormone replacement; further studies are needed.

**Clinical Manifestations**

Most infants with congenital hypothyroidism are asymptomatic at birth, even if there is complete agenesis of the thyroid gland. This situation is attributed to partial transplacental passage of maternal T₄, which provides fetal levels that are approximately 33% of normal at birth. Despite this maternal contribution of T₄, hypothyroid infants still have a low serum T₄ and elevated TSH level and so will be identified by newborn screening programs.

The clinician depends on neonatal screening tests for the diagnosis of congenital hypothyroidism. Some babies escape newborn screening, and laboratory errors occur, so awareness of early symptoms and signs must be maintained. Congenital hypothyroidism caused by thyroid dysgenesis, the most common etiology, is twice as common in girls as in boys. Before neonatal screening programs, congenital hypothyroidism was rarely recognized in the newborn because the signs and symptoms are usually not sufficiently developed. It can be suspected and the diagnosis established during the early weeks of life if the initial, but less characteristic, manifestations are recognized. Birthweight and length are normal, but head size may be slightly increased because of myxedema of the brain. The anterior and posterior fontanels are open widely; observation of this sign at birth can serve as an initial clue to the early recognition of congenital hypothyroidism. Only 3% of normal newborn infants have a posterior fontanel larger than 0.5 cm. Prolongation of physiologic jaundice, caused by delayed maturation of glucuronide conjugation, may be the earliest sign. Feeding difficulties, especially sluggishness, lack of interest, somnolence, and choking spells during nursing, are often present during the 1st mo of life. Respiratory difficulties, partly caused by the large tongue, include apneic episodes, noisy respirations, and nasal obstruction. Some infants may develop respiratory distress syndrome. Affected infants cry little, sleep much, have poor appetites, and are generally sluggish. There may be constipation that does not usually respond to treatment. The abdomen is large, and an umbilical hernia is usually present. The temperature is subnormal, often <35°C (95°F), and the skin, particularly that of the extremities, may be cold and mottled. Edema of the genitals and extremities may be present. The pulse is slow, and heart murmurs, cardiomegaly, and asymptomatic pericardial effusion are common. Macrocytic anemia is often present and is refractory to treatment with hematinics. Because symptoms appear gradually, the clinical diagnosis is often delayed.

Approximately 10% of infants with congenital hypothyroidism have associated congenital anomalies. Cardiac anomalies are most common, but anomalies of the nervous system and eye have also been reported. Infants with congenital hypothyroidism may have associated hearing loss. As noted under “Etiology” above, specific mutations in genes involved in thyroid gland development result in “spondric” congenital hypothyroidism. Mutations in **NKX2.1 (TTF-1)**, present in the thyroid gland, lungs, and brain, are characterized by congenital hypothyroidism, respiratory distress syndrome, and ataxia, or even choreoathetosis. Mutations in **NKX2.5** result in congenital hypothyroidism and associated congenital heart defects. Mutations in **TTF-2**, present in the thyroid gland, palate, and hair, include congenital hypothyroidism, cleft palate, and spiky hair. Mutations in **PAX-8**, present in the thyroid gland and kidneys, present with congenital hypothyroidism and genitourinary anomalies, including renal agenesis.

If congenital hypothyroidism goes undetected and untreated, these manifestations progress. Retardation of physical and mental development becomes greater during the following months, and by 3–6 mo of age the clinical picture is fully developed (Fig. 565-1). When there is only partial deficiency of thyroid hormone, the symptoms may be milder, the syndrome incomplete, and the onset delayed. Although breast milk contains significant amounts of thyroid hormones,
Affected children come to clinical attention because of a growing mass of tissue that secretes abnormal amounts of one of the thyroid hormones for many years, or it eventually fails in early childhood. Ectopic thyroid tissue (lingual, sublingual, subhyoid) produce adequate amounts of thyroid hormone at birth and so are not identified by newborn screening programs. In particular, some children with ectopic thyroid tissue may not take place at all.

Boys are more prone to development of the syndrome, which has been associated with muscular pseudohypertrophy occurring in siblings born from a consanguineous mating. Affected older children can have an athletic appearance at the base of the tongue or in the midline of the neck, usually at the level of the hyoid. Occasionally, ectopia is associated with thyroglossal duct cysts. It can occur in siblings. Surgical removal of ectopic thyroid tissue from a euthyroid patient usually results in hypothyroidism, because most such patients have no other thyroid tissue.

Laboratory Findings

In developed countries, infants with congenital hypothyroidism are identified by newborn screening programs. Blood obtained by heel-prick between 2 and 5 days of life is placed on a filter paper card and sent to a central screening laboratory. The early approach to newborn screening in North America and Europe began with measurement of levels of T4, followed by measurement of TSH when T4 is low. This approach identifies infants with primary hypothyroidism, some with central or hypothalamic hypothyroidism, and infants with a delayed elevation in TSH levels. Over time, many neonatal screening programs in North America, Europe, and elsewhere in the world have switched to an initial TSH measurement. This approach will detect infants with primary hypothyroidism and infants with milder, subclinical hypothyroidism (normal T4, elevated TSH), but it may not detect infants with delayed TSH elevation or with central or hypothalamic hypothyroidism. With any of these tests, special care should be given to the normal range of values for age of the patient, particularly in the first weeks of life (Table 565-2).

Regardless of the approach used for screening, some infants escape detection because of technical or human errors; clinicians must maintain their vigilance for clinical manifestations of hypothyroidism.

Serum levels of T4 or free T4 are low; serum levels of T3 may be normal and are not helpful in the diagnosis. If the defect is primarily in the thyroid, levels of TSH are elevated, often to >100 mU/L. Serum levels of thyroglobulin are usually low in infants with thyroid agenesis or defects of thyroglobulin synthesis or secretion, whereas they are elevated with ectopic glands and other inborn errors of T4 synthesis, but there is a wide overlap of ranges.

Special attention should be paid to identical twins; in several reported cases, neonatal screening failed to detect the affected twin with hypothyroidism, and the diagnosis was not made until the infants were 4-5 mo of age. In these cases, transfusion of euthyroid blood from the unaffected twin normalized the serum levels of T4 and TSH in the

**Figure 565-1** Congenital hypothyroidism in an infant 6 mo of age. The infant ate poorly in the neonatal period and was constipated. She had a persistent nasal discharge and a large tongue; she was very lethargic and had no social smile and no head control. A, Notice the puffy face, dull expression, and hirsute forehead. Tests revealed a negligible uptake of radioiodine. Osseous development was that of a newborn. B, Four mo after treatment, note the decreased puffiness of the face, the decreased hirsutism of the forehead, and the alert appearance.

affected twin at the initial screening. Many newborn screening programs perform a routine second test in same-sex twins.

Retardation of osseous development can be shown radiographically at birth in approximately 60% of congenitally hypothyroid infants and indicates some deprivation of thyroid hormone during intrauterine life. The distal femoral and proximal tibial epiphyses, normally present at birth, are often absent (Fig. 565-2A). In undetected and untreated patients, the discrepancy between chronologic age and osseous development increases. The epiphyses often have multiple foci of ossification (epiphyseal dysgenesis; Fig. 565-2B); deformity
A \textbf{B} \begin{flushright} Figure 565-2 Congenital hypothyroidism. \textit{A}, Absence of distal femoral epiphysis in a 3 mo old infant who was born at term. This is evidence for the onset of the hypothyroid state during fetal life. \textit{B}, Epiphysal dysgenesis in the head of the humerus in a 9 yr old girl who had been inadequately treated with thyroid hormone. \end{flushright} "beaking") of the 12th thoracic or 1st or 2nd lumbar vertebra is common. X-rays of the skull show large fontanels and wide sutures; intersutural (wormian) bones are common. The sella turcica is often enlarged and round; in rare instances, there may be erosion and thinning. Formation of teeth can be delayed. Cardiac enlargement or pericardial effusion may be present.

Scintigraphy can help to pinpoint the underlying cause in infants with congenital hypothyroidism, but treatment should not be unduly delayed for this study. $^{123}$I-sodium iodide is superior to $^{99m}$Tc-sodium pertechnetate for this purpose. Ultrasonographic examination of the thyroid is helpful, but studies show it can miss some ectopic glands shown by scintigraphy. Demonstration of ectopic thyroid tissue is diagnostic of thyroid dysgenesis and establishes the need for lifelong treatment with T$_4$. Failure to demonstrate any thyroid tissue suggests thyroid aplasia, but this also occurs in neonates with hypothyroidism caused by maternal TRBAb and in infants with the iodide-trapping defect. A normally situated thyroid gland with a normal or avid uptake of radionuclide indicates a defect in thyroid hormone biosynthesis. In the past, patients with goitrous hypothyroidism have required extensive evaluation, including radiiodine studies, perchlorate discharge tests, kinetic studies, chromatography, and studies of thyroid tissue, to determine the biochemical nature of the defect. Most can be evaluated by genetic studies looking for a suspected mutation in the steps along the T$_4$ biosynthetic pathway.

The electrocardiogram may show low-voltage P and T waves with diminished amplitude of QRS complexes and suggest poor left ventricular function and pericardial effusion. Echocardiography can confirm a pericardial effusion. The electroencephalogram often shows low voltage. In children older than 2 yr of age, the serum cholesterol level is usually elevated. Brain MRI before treatment is reportedly normal, although proton magnetic resonance spectroscopy shows high levels of choline-containing compounds, which can reflect blocks in myelin maturation.

\section*{Treatment}

Levothyroxine (l-T$_4$) given orally is the treatment of choice. Although T$_4$ is the biologically active form of thyroid hormone, most of the T$_4$ in the brain is formed from local deiodination of T$_4$. Because 80% of circulating T$_4$ is formed by monodeiodination of T$_4$, serum levels of T$_4$ and T$_3$ return to normal with l-T$_4$ treatment alone. The recommended initial starting dose is 10-15 \(\mu\)g/kg/day (totaling 37.5-50.0 \(\mu\)g/day for most term infants). The starting dose can be tailored to the severity of hypothyroidism. Rapid normalization of thyroid function has been demonstrated to be important in achieving optimal neurodevelopmental outcome. Newborns with more severe hypothyroidism, as judged by a serum T$_4$ <5 \(\mu\)g/dL and/or imaging studies confirming aplasia, should be started at the higher end of the dosage range.

l-T$_4$ is available only in tablet form in the United States; there is an approved liquid l-T$_4$ preparation in Europe. The daily tablets should be crushed and mixed with a small volume of liquid. l-T$_4$ tablets should not be mixed with soy protein formulas, concentrated iron, or calcium, because these can bind T$_4$ and inhibit its absorption. Although it is recommended to administer l-T$_4$ on an empty stomach and avoid food for 30-60 min, this is not practical in an infant. As long as the method of administration is consistent day to day, dosing can be adjusted based on serum thyroid test results to achieve the desired treatment goals.

Levels of serum T$_4$ or free T$_4$ and TSH should be monitored at recommended intervals (every 1-2 mo in the 1st 6 mo of life, and then every 2-4 mo between 6 mo and 3 yr of age). The goals of treatment are to maintain the serum free T$_4$ or total T$_4$ in the upper half of the reference range for age (see Table 565-2), with serum TSH in the reference range for age, optimally 0.5-2.0 mU/L. The dose of l-T$_4$ on a weight basis gradually decreases with age.

Later, confirmation of the diagnosis may be necessary for some infants to rule out the possibility of transient hypothyroidism. This is unnecessary in infants with proven thyroid ectopia or in those who manifest elevated levels of TSH after 6-12 mo of therapy because of poor compliance or an inadequate dose of T$_4$. Discontinuation of therapy at about 3 yr of age for 3-4 wk results in a marked increase in TSH levels in children with permanent hypothyroidism.

Care should be taken to avoid prolonged undertreatment or overtreatment. The only untoward effects of l-T$_4$ are related to its dosage. Overtreatment can risk craniostenosis and temperament problems.

\section*{Prognosis}

Thyroid hormone is critical for normal cerebral development in the early postnatal months; biochemical diagnosis must be made soon after birth, and effective treatment must be initiated promptly to prevent irreversible brain damage. With the advent of neonatal screening programs for detection of congenital hypothyroidism, the prognosis for affected infants has improved dramatically. Early diagnosis and adequate treatment from the 1st weeks of life result in normal linear growth and development. Most studies report that psychometric testing in infants detected by newborn screening shows verbal, psychomotor, and global IQ scores similar to those of unaffected siblings or classmate controls. Some screening programs report that the most severely affected infants, as judged by the lowest T$_4$ levels and retarded skeletal maturation, have reduced IQs (by 5-20 points) and other neuropsychologic sequelae, such as incoordination, hypotonia or hypertonia, short attention span, and speech problems, even with early diagnosis and
adequate treatment. Psychometric testing can show problems with vocabulary and reading comprehension, arithmetic, and memory. Approximately 20% of children have a neurosensory hearing deficit. Outcome studies in adults, detected and treated as neonates, reveal delayed social development, lower self-esteem, and a lower health-related quality of life. The latter appears to be related to those individuals with lower neurocognitive outcome and associated congenital malformations.

Delay in diagnosis, failure to correct initial hypothyroxinemia rapidly, inadequate treatment, and poor compliance in the 1st 2-3 yr of life result in variable degrees of brain damage. Without treatment, affected infants are profoundly intellectually challenged and growth retarded. When onset of hypothyroidism occurs after 2 yr of age, the outlook for normal development is much better even if diagnosis and treatment have been delayed, indicating how much more important thyroid hormone is to the rapidly growing brain of the infant.

**ACQUIRED HYPOTHYROIDISM**

**Epidemiology**

Studies of school-age children report that hypothyroidism occurs in approximately 0.3% (1 in 333). Subclinical hypothyroidism (TSH >4.5 mU/L, normal T₄ or free T₃) is more common, occurring in approximately 2% of adolescents. Acquired hypothyroidism is most commonly a result of chronic lymphocytic thyroiditis; 6% of children and 3% of adults have evidence of autoimmune thyroid disease, which occurs with a 2:1 female: male preponderance.

**Etiology**

The most common cause of acquired hypothyroidism (Table 565-3) is chronic lymphocytic (Hashimoto) thyroiditis (see Chapter 566). **Autoimmune thyroid disease** may be part of polyglandular syndromes; children with Down and Turner syndrome, possibly Klinefelter syndrome, and celiac disease or diabetes are at higher risk for associated autoimmune thyroid disease (see Chapter 566) as are those with **autoimmune polyglandular syndromes (APSs)** (Tables 565-4 and 565-5).

APS has 4 types, but APS-1 and APS-2 are the most common. APS-1 includes 2 components of the triad of hypoparathyroidism, Addison disease (adrenal insufficiency) and mucocutaneous candidiasis (“HAM” syndrome). Commonly referred to by the acronym APECED (autoimmune polyglandular disease and IgG 4-related endocrinopathies: pathophysiology and clinical characteristics). It is autosomal recessive, caused by a mutation in the AIRE (autoimmune regulator) gene. Less-common features include thyroiditis (~10%), type 1 diabetes mellitus, primary hypogonadism, pernicious anemia, vitiligo, alopecia, chronic active hepatitis, and malabsorption syndrome.

**APS-2** (Schmidt syndrome) most commonly consists of autoimmune thyroiditis (~70%), Addison disease, and type 1 diabetes mellitus. Less-common features include primary hypogonadism, pernicious anemia, and vitiligo. APS-2 occurs more commonly than APS-1, generally presents in early adulthood, and has a female preponderance. The underlying immunologic defect remains to be determined.

*ATPase, adenosine triphosphatase; TSH, thyroid-stimulating hormone.*

In children with Down syndrome, antithyroid antibodies develop in approximately 30%, and subclinical or overt hypothyroidism occurs in approximately 15-20%. In girls with Turner syndrome, antithyroid antibodies develop in approximately 40%, and subclinical or overt hypothyroidism occurs in approximately 15-30%, rising with increasing age. In children with type 1 diabetes mellitus, approximately 20% develop antithyroid antibodies and 5% become hypothyroid. Additional autoimmune diseases with an increased risk of hypothyroidism include immune dysregulation–polyendocrinopathy–enteropathy–X-linked syndrome (IPEX) and IPEX-like disorders, immunoglobulin G₆-related diseases, Sturge syndrome, multiple sclerosis, pernicious anemia, Addison disease, and ovarian failure. Although typically seen in adolescence, it occurs as early as in the 1st yr of life. Williams syndrome is associated with subclinical hypothyroidism; this does not appear to be autoimmune, as antithyroid antibodies are negative.

Protracted ingestion of medications containing iodides—for example, expectorants or nutritional supplements—can cause hypothyroidism, usually accompanied by goiter (see Chapter 567). Amiodarone, a drug used for cardiac arrhythmias and consisting of 37% iodine by weight, causes hypothyroidism in approximately 20% of treated children. It affects thyroid function directly by its high iodine content as well as by inhibition of 5′-deiodinase, which converts T₄ to T₃. Children treated with this drug should have serial measurements of T₉, T₃, and TSH.

Anticonvulsants, including phenytoin, phenobarbital, and valproate, may cause thyroid dysfunction, usually mild, subclinical hypothyroidism. Certain anticonvulsants stimulate hepatic P450 metabolism and excretion of T₄. Children with Graves disease treated with antithyroid drugs (methimazole or propylthiouracil) can develop hypothyroidism. Additional drugs that can produce hypothyroidism include lithium, tyrosine kinase inhibitors, interferon-α, stavudine, thalidomide, and aminoglutethimide.

Children who receive craniospinal irradiation, as with treatment of Hodgkin disease or other head and neck malignancies or that is administered before bone marrow transplantation, are at risk for thyroid damage. Approximately 30% of such children acquire elevated TSH levels within a year after therapy, and another 15-20% progress to hypothyroidism within 5-7 yr. Central (hypothalamic) hypothyroidism may develop in approximately 10% of children receiving craniospinal irradiation.

Radioactive iodine ablative treatment or thyroidectomy for Graves disease or cancer results in hypothyroidism, as can removal of ectopic thyroid tissue. Thyroid tissue in a thyroglossal duct cyst usually constitutes the only source of thyroid hormone, and excision results in hypothyroidism. Ultrasonographic examination or a radionuclide scan before surgery is indicated in these patients.

Children with nephrogenic cystinosis, a disorder characterized by intralysosomal storage of cystine in body tissues, acquire impaired thyroid function. Hypothyroidism may be overt, but subclinical forms are more common, and periodic assessment of TSH levels is indicated. By 13 yr of age, two thirds of these patients require T₄ replacement.

Histiocytic infiltration of the thyroid in children with Langerhans cell histiocytosis (see Chapter 507) can result in hypothyroidism. Children with chronic hepatitis C infection are at risk for subclinical hypothyroidism; this does not appear to be autoimmune, because antithyroid antibodies are negative.

Hypothyroidism can occur in children with large hemangiomata of the liver, because of increased type 3 deiodinase activity, which catalyzes conversion of T₄ to reverse T₃, and T₃ to diiodothyronine. Thyroid secretion is increased, but it is not sufficient to compensate for the large increase in degradation of T₄ to reverse T₃.

Some patients with congenital thyroid dysgenesis and residual thyroid function or with incomplete genetic defects in thyroid hormone synthesis do not display clinical manifestations until childhood and appear to have acquired hypothyroidism. Although these conditions are usually now detected by newborn screening programs, very mild defects can escape detection.

Any hypothalamic or pituitary disease can cause acquired central hypothyroidism (see Chapter 557). TSH deficiency may be the result of a hypothalamic-pituitary tumor (craniopharyngioma is most common in children) or a result of treatment for the tumor. Other causes include cranial radiation, head trauma, or diseases infiltrating the pituitary gland, such as Langerhans cell histiocytosis.

**Clinical Manifestations**

Deceleration of growth is usually the first clinical manifestation, but this sign often goes unrecognized (Figs. 565-3 and 565-4). Goiter associated with Hashimoto thyroiditis, which may be a presenting feature, is typically non tender and firm, with a rubbery consistency and a pebbly surface. Weight gain is mostly fluid retention (myxedema), not true obesity. Myxedematous changes of the skin, constipation, cold intolerance, decreased energy, and an increased need for sleep develop insidiously. Surprisingly, schoolwork and grades usually do not suffer, even in severely hypothyroid children. Additional features include bradycardia, muscle weakness or cramps, nerve entrapment, and ataxia. Osseous maturation is delayed, often strikingly, which is an indication of the duration of the hypothyroidism. Adolescents typically have delayed puberty; older adolescent girls manifest menometrorrhagia. Younger children might present with galactorrhea or pseudoprecocious puberty. Galactorrhea is a result of increased TRH stimulating prolactin secretion. The precocious puberty, characterized by breast development and vaginal bleeding in girls and macroorchidism in boys, is thought to be the result of abnormally high TSH concentrations binding to the follicle-stimulating hormone receptor with subsequent stimulation.

Some children have headaches and vision problems; they usually have enlargement of the pituitary gland, sometimes with suprassellar extension, after long-standing primary hypothyroidism. This condition, believed to be the result of thyrotophy hyperplasia, may be mistaken for a pituitary tumor (see Chapter 557). Abnormal laboratory studies include hypernatremia, macrocytic anemia, hypercholesterolemia, and elevated creatine phosphokinase. Table 565-6 lists the complications seen in severe hypothyroidism. All these changes return to normal with adequate replacement of T₄.

**Diagnostic Studies**

Children with suspected hypothyroidism should undergo measurement of serum free T₄ and TSH. Because the normal range for thyroid tests is slightly higher in children than adults, it is important to compare results to age-specific reference ranges. Measurement of antithyroglobulin and antiperoxidase antibodies can pinpoint autoimmune thyroiditis as the cause. In cases with a goiter resulting from autoimmune thyroid disease, an ultrasound examination typically shows diffuse enlargement with scattered hypoechogenicity. However, generally, sonography is not indicated unless there is a suspicion of a thyroid nodule on neck palpation. In such cases, ultrasound examination is the most accurate study to confirm the presence of a nodule and determine if other smaller nodules are present. In addition, an ultrasound examination can determine the nodule dimensions, texture (solid vs cystic nature), and presence or absence of other features that might influence a decision to undertake fine-needle aspiration, such as microcalcifications, blurred margins, “taller-than-wide” shape, intranodular vascular flow, and pathologic-appearing adjacent lymph nodes (see Chapter 569.1). In children with a nodule and suppressed TSH, a radioactive iodine uptake scan is indicated to determine if this is a “hot” or hyperfunctioning nodule. A bone age x-ray at diagnosis is useful, in that the degree of delay approximates duration and severity of hypothyroidism.

**Treatment and Prognosis**

L-T₄ is the treatment of choice in children with hypothyroidism. The dose on a weight basis gradually decreases with age. For children age 1-3 yr, the average L-T₄ dosage is 4-6 µg/kg/day; for age 3-10 yr, 3-5 µg/kg/day; and for age 10-16 yr, 2-4 µg/kg/day. Treatment should be monitored by measuring serum free T₄ and TSH every 4-6 mo as well as 6 wk after any change in dosage. In children with central hypothyroidism, where TSH levels are not helpful in monitoring treatment, the goal should be to maintain serum free T₄ in the upper half of the normal reference range for age.

During the 1st yr of treatment, deterioration of schoolwork, poor sleeping habits, restlessness, short attention span, and behavioral
Figure 565-3  A, Acquired hypothyroidism in a girl 6 yr of age. She was treated with a wide variety of hematinsics for refractory anemia for 3 yr. She had almost complete cessation of growth, constipation, and sluggishness for 3 yr. The height age was 3 yr; the bone age was 4 yr. She had a sallow complexion and immature facies with a poorly developed nasal bridge. Serum cholesterol, 501 mg/dL; radioiodine uptake, 7% at 24 hr; protein-bound iodine (PBI), 2.8 mg/dL.  B, After therapy for 18 mo, note the nasal development, increased luster and decreased pigmentation of hair, and maturation of the face. The height age was 5.5 yr; the bone age was 7 yr. There was a decided improvement in her general condition. Menarche occurred at 14 yr. The ultimate height was 155 cm (61 in). She graduated from high school. The disorder was well controlled with sodium-L-thyroxine daily.

Figure 565-4  A, Short stature (108 cm, <3rd percentile), generalized myxedema, sleepy expression, protuberant abdomen, and coarse hair are signs of hypothyroidism in this 12 yr old boy. Body proportions are immature for his age (1.25:1).  B, Same boy 4 mo after treatment. His height increased by 4 cm; note the marked change in body habitus owing to loss of generalized myxedema, improved muscle tone, and bright facial expression. (From LaFranchi SH: Hypothyroidism, Pediatr Clin North Am 26:33-51, 1979.)
problems might ensue, but these are transient; forewarning families about these manifestations enhances appropriate management. These may partially be ameliorated by starting at subreplacement T₄ doses and advancing slowly. The development of persistent headaches or vision changes should prompt an evaluation for papilledema associated with pseudotumor cerebri, a rare complication following initiation of L-T₄ treatment in older children (age 8-13 yr).

In older children, after catch-up growth is complete, the growth rate provides a good index of the adequacy of therapy. Periodic bone age x-rays are useful to monitor treatment and future growth potential. In children with long-standing hypothyroidism, catch-up growth may be incomplete (see Fig. 565-4). During the 1st 18 mo of treatment, skeletal maturation often exceeds expected linear growth, resulting in a loss of approximately 7 cm of predicted adult height.

Congenital Hypothyroidism

Acquired Hypothyroidism

Antibodies to pendrin, an apical protein on thyroid follicular cells, have been demonstrated in 80% of children with autoimmune thyroiditis. Antibodies also have been found against the sodium–iodide symporter, but their pathogenic role is unclear.

**Clinical Manifestations**

The disorder is 4-6 times more common in girls than in boys. It can occur during the 1st 3 yr of life, but becomes sharply more common after 6 yr of age and reaches a peak incidence during adolescence. The most common clinical manifestations are goiter and growth retardation. The goiter can appear insidiously and may be small or large. In most patients, the thyroid is diffusely enlarged, firm, and nontender. In approximately 30% of patients, the gland is asymmetric and can seem to be nodular. Most of the affected children are clinically euthyroid and asymptomatic; some may have symptoms of pressure in the neck, including difficulty swallowing and shortness of breath. Some children have clinical signs of hypothyroidism, but others who appear clinically euthyroid have laboratory evidence of hypothyroidism. A few children have manifestations suggesting hyperthyroidism, such as nervousness, irritability, increased sweating, and hyperactivity, but results of laboratory studies are not necessarily those of hyperthyroidism. Occasionally, the disorder coexists with Graves disease (“Hashitoxicosis”). Ophthalmopathy can occur in autoimmune thyroiditis in the absence of Graves disease.

The clinical course is variable. The goiter might become smaller or might disappear spontaneously, or it might persist unchanged for years while the patient remains euthyroid. Most children who are euthyroid at presentation remain euthyroid, although a percentage of patients acquire hyperthyroidism gradually within months or years. In children who initially have mild or subclinical hypothyroidism (elevated serum TSH, normal free thyroxine [T₄] level), over several years approximately 40% revert to euthyroidism, 50% continue to have subclinical hypothyroidism, and approximately 10% develop overt hypothyroidism (elevated serum TSH, subnormal free T₄ level). Chronic lymphocytic thyroiditis is the cause of most cases of nongoitrous (atrophic) hypothyroidism.

Familial clusters of chronic lymphocytic thyroiditis are common; the incidence in siblings or parents of affected children may be as high as 25%. TPO-Abs and anti-Tg Abs in these families appear to be inherited in an autosomal dominant fashion, with reduced penetrance in males. The concurrence within families of patients with chronic lymphocytic thyroiditis, hypothyroidism, and Graves disease provides cogent evidence for a basic relationship among these 3 conditions.

The disorder is associated with many other autoimmune disorders. Autoimmune thyroiditis occurs in 10% of patients with type 1 autoimmune polyendocrine syndrome (APS-1), characterized by autoimmune polyendocrinopathy, candidiasis, and ectodermal dysplasia (APECED). APS-1 consists of 2 of the triad of hypoparathyroidism, Addison disease, and mucocutaneous candidiasis (HAM syndrome). This relatively rare autosomal recessive disorder occurs in childhood and is caused by mutations in the autoimmune regulator (AIRE) gene on chromosome 21q22.3.

Autoimmune thyroid disease occurs in 70% of patients with APS-2. APS-2 consists of the association of autoimmune thyroiditis and Addison disease (Schmidt syndrome) or autoimmune thyroiditis with type 1 diabetes mellitus (Carpenter syndrome). It typically occurs in later childhood or early adulthood; the etiology is unknown. Autoimmune thyroiditis has been described in children with immunodysregulation polyendocrinopathy enteropathy X-linked (IPEX) syndrome, which includes early-onset diabetes and colitis. Autoimmune thyroid disease also tends to be associated with pernicious anemia, vitiligo, or alopecia. TPO-Abs are found in approximately 20% of white and 4% of black children with type 1 diabetes mellitus. Autoimmune thyroid disease has an increased incidence in children with congenital rubella.

Chronic lymphocytic thyroiditis also is associated with certain chromosomal disorders, particularly Turner syndrome and Down syndrome. In children with Down syndrome, one study reported that 28% had antithyroid antibodies (predominantly anti-TPOs), 7% had subclinical hypothyroidism, 7% had overt hypothyroidism, and 5% had...
hypothyroidism. In a study of girls with Turner syndrome, 41% had antithyroid antibodies (again, predominantly anti-TPOs), 18% had goiter, and 8% had subclinical or overt hypothyroidism. Another study of 75 girls with Turner syndrome found that autoimmune thyroid disease increased from the 1st (15%) to the 3rd (30%) decade of life. Boys with Klinefelter syndrome appear to be at risk for autoimmune thyroid disease. Table 566-1 compares the characteristics of Hashimoto thyroiditis to other thyroiditis syndromes.

**Laboratory Findings**

Thyroid function tests (free T4 and TSH) are often normal, although the level of TSH may be slightly or even moderately elevated in some patients, which is termed subclinical hypothyroidism. That many children with chronic lymphocytic thyroiditis do not have elevated levels of TSH indicates that the goiter is caused by the lymphocytic infiltrations or by thyroid growth-stimulating immunoglobulins. Young children with chronic lymphocytic thyroiditis have serum TPO-Abs, but the anti-Tg Abs are positive in <50%. TPO-Abs and anti-Tg Abs are found equally in adolescents with chronic lymphocytic thyroiditis. When both tests are used, approximately 95% of patients with thyroid autoimmunity are detected. Levels in children and adolescents are lower than those in adults with Hashimoto thyroiditis, and repeated measurements are indicated in questionable instances because titers might increase later in the course of the disease. In adolescent females with overt hypothyroidism, measurement of TSH receptor–blocking antibodies may identify patients at future risk of having babies with transient congenital hypothyroidism.

Thyroid scans and ultrasonography usually are not needed. If they are done, thyroid scans reveal irregular and patchy distribution of the radioisotope, and in approximately 60% or more, the administration of perchlorate results in a >10% discharge of iodide from the thyroid gland. Thyroid ultrasonography shows heterogeneous echogenicity in most patients, along with an increased number of benign-appearing hyperplastic lymph nodes in the neck. The definitive diagnosis can be established by biopsy of the thyroid; this procedure is rarely clinically indicated.

Antithyroid antibodies also may be found in almost 50% of the siblings of affected patients and in a significant percentage of the mothers of children with Down syndrome or Turner syndrome without demonstrable thyroid disease.

**Treatment**

If there is evidence of overt hypothyroidism (elevated TSH, low T4 or free T4), replacement treatment with levothyroxine (at doses specific for size and age) is indicated. The goiter usually shows some decrease in size but can persist for years. In an euthyroid patient, treatment with suppressive doses of levothyroxine is unlikely to lead to a significant decrease in size of the goiter. Antibody levels fluctuate in both treated and untreated patients and persist for years. Because the disease is self-limited in some instances, the need for continued therapy requires periodic reevaluation. Untreated patients should also be checked periodically. Although there is some controversy about treating patients with subclinical hypothyroidism (elevated TSH, normal T4, or low T4), many clinicians prefer to treat such children until growth and puberty are complete, and then reevaluate their thyroid function.

Prominent nodules (i.e., >1 cm) that persist despite suppressive therapy should be examined histologically using fine-needle aspiration, because thyroid carcinoma or lymphoma has occurred in patients with Hashimoto thyroiditis.

Goiter

Stephen A. Huang and Stephen H. LaFranchi

A goiter, or thyromegaly, is an enlargement of the thyroid gland. Persons with enlarged thyroids can have normal function of the gland (euthyroidism), thyroid deficiency (hypothyroidism), or overproduction of the hormones (hyperthyroidism). Goiter may be congenital or acquired, endemic or sporadic. Detection of a goiter should prompt an investigation of its cause and the assessment of thyroid function.

Goiter most often results from the increased pituitary secretion of thyroid-stimulating hormone (TSH) in response to decreased circulating levels of thyroid hormones. Activation of the TSH receptor from thyrotropin receptor–stimulating antibodies (in Graves disease), gain-of-function TSH receptor mutations, or inappropriate TSH secretion (from dominant negative thyroid hormone receptor mutations or TSH-secreting adenomas) can also cause thyromegaly. Thyroid enlargement can also result from infiltrative processes that may be inflammatory or neoplastic.

567.1 Congenital Goiter

Stephen A. Huang and Stephen H. LaFranchi

Congenital goiter is usually sporadic and can result from a fetal thyroxine (T4) synthetic defect or from administration of antithyroid drugs or iodides during pregnancy for the treatment of maternal thyrotoxicosis. Goitrogenic drugs that cross the placenta at high doses can interfere with synthesis of thyroid hormone, resulting in goiter and hypothyroidism in the fetus. These effects are most severe when pharmacologic overtreatment with antithyroid drugs causes concomitant hypothyroidism in the mother and reduces the supply of maternal thyroid hormone available to the fetus. In women with Graves disease receiving antithyroid drugs, fetal effects can occur when the mother takes propylthiouracil at only 100-200 mg/24 hr; consequently, all infants born to women treated with antithyroid drugs in the 3rd trimester should undergo thyroid studies at birth. Even when the infant is clinically euthyroid, there may be retardation of osseous maturation, low levels of T4, and elevated levels of TSH. Administration of thyroid hormone to affected infants may be indicated to treat clinical hypothyroidism, to hasten the disappearance of the goiter, and to prevent brain damage. Because the condition is rarely permanent, thyroid hormone may be safely discontinued after the antithyroid drug has been excreted by the neonate, usually after 1-2 wk. In addition to antithyroid medications, iodides are included in many proprietary cough preparations used to treat asthma; these preparations should be avoided during pregnancy because they have often been reported to cause congenital goiter. Amiodarone, an antiarrhythmic drug with 37% iodine content, has also caused congenital goiter with hypothyroidism.

Enlargement of the thyroid at birth may occasionally be sufficient to cause respiratory distress that interferes with nursing and can even cause death. The head may be maintained in extreme hyperextension. In pregnant women who are overtreated with antithyroid drugs, the prenatal diagnosis of even massive fetal goiter can often be corrected by withdrawal of the maternal medication, with or without intraamniotic thyroid hormone injection. When postnatal respiratory obstruction is severe, partial thyroidectomy rather than tracheostomy is indicated (Fig. 567-1).

Goiter is almost always present in the infant with neonatal Graves hyperthyroidism. Thyroid enlargement results from transplacental passage of maternal thyroid-stimulating immunoglobulin (see Chapter 568.2). These goiters usually are not large; the infant manifests clinical symptoms of hyperthyroidism. The mother often has a history of Graves disease, or the diagnosis of maternal Graves may be revealed through the evaluation of neonatal hyperthyroidism. TSH receptor–activating mutations are also a recognized cause of congenital goiter and hyperthyroidism.

When no causative factor is identifiable from the maternal or medication history, a defect in synthesis of thyroid hormone should be suspected. Neonatal screening programs find congenital hypothyroidism caused by such a defect in 1 in 30,000-50,000 live births. It is advisable to treat immediately with thyroid hormone and to postpone more-detailed studies for later in life. If a specific defect is suspected,
genetic tests to identify a mutation may be undertaken (see Chapter 565). Because these defects are often caused by recessive mutations, a precise diagnosis is helpful for genetic counseling. Monitoring subsequent pregnancies with ultrasonography can be useful in detecting fetal goiters (see Chapter 96).

**Pendred syndrome**, characterized by familial goiter and neurosensory deafness, is caused by a mutation in the SLC26A4 gene, which encodes the pendrin chloride–iodide transport protein expressed in the thyroid gland and cochlea. This defect results in abnormal iodide organization in the thyroid and can cause a goiter at birth. The more common presentation is a euthyroid goiter and sensorineural hearing loss later in life.

**Iodine deficiency** as a cause of congenital goiter is rare in developed countries but persists in isolated endemic areas (see Chapter 567.3). More important is the recognition that severe iodine deficiency early in pregnancy can cause neurologic damage during fetal development, even in the absence of goiter. The iodine deficiency can result in combined maternal and fetal hypothyroidism, reducing the protective transfer of maternal thyroid hormones. When the “goiter” is lobulated, asymmetric, firm, or large to an unusual degree, a teratoma within or in the vicinity of the thyroid must be considered in the differential diagnosis (see Chapter 569).

**Bibliography** is available at Expert Consult.

## 567.2 Intratracheal Goiter

**Stephen A. Huang and Stephen H. LaFranchi**

One of the many ectopic locations of thyroid tissue is within the trachea. The intraluminal thyroid lies beneath the tracheal mucosa and is often continuous with the normally situated extratracheal thyroid gland. The thyroid is susceptible to goitrous enlargement, which involves both the eutopic and ectopic thyroid tissue. When there is obstruction of the airway associated with a goiter, it must be ascertained whether the obstruction is extratracheal or endotracheal. If obstructive manifestations are mild, administration of sodium l-thyroxine (levothyroxine) usually causes the goiter to decrease in size. When symptoms are severe, surgical removal of the endotracheal goiter is indicated.

## 567.3 Endemic Goiter and Cretinism

**Stephen A. Huang and Stephen H. LaFranchi**

**Etiology**

The association between dietary deficiency of iodine and the prevalence of goiter or cretinism is well established. A moderate deficiency of iodine can be overcome by increased efficiency in the synthesis of thyroid hormone. Iodine liberated in the tissues is returned rapidly to the gland, which resynthesizes triiodothyronine (T3) preferentially at a higher rate than normal. This increased activity is achieved by compensatory hypertrophy and hyperplasia (goiter), which satisfy the demands of the tissues for thyroid hormone. In geographic areas where deficiency of iodine is severe, decompensation and hypothyroidism can result. Recent estimates from the World Health Organization indicate that nearly 2 billion individuals currently have insufficient iodine intake, including one third of the world’s school-age children. Thus, despite great progress in the global effort to reduce iodine deficiency, it remains the leading cause of preventable intellectual disability worldwide.

Seawater is rich in iodine; the iodine content of fish and shellfish is also high. As a result, endemic goiter is rare in populations living along the coast. Iodine is deficient in the water and native foods in the Pacific West and the Great Lakes areas of the United States. Deficiency of dietary iodine is even greater in certain Alpine valleys, the Himalayas, the Andes, the Congo, and the highlands of Papua New Guinea. In areas such as the United States, where iodine is provided in foods from other areas and in iodized salt, endemic goiter has disappeared. Iodized salt in the United States contains potassium iodide (100 µg/g), which provides excellent prophylaxis. Further iodine intake in the United States is contributed by iodates used in baking, iodine-containing coloring agents, and iodine-containing disinfectants used in the dairy industry. The recommended daily allowance of iodine is as follows:

- Children younger than 2 yr: ≥100µg/day
- School-age children: 100–299µg/day
- Pregnant women: ≥150µg/day
- Lactating women: ≥100µg/day

While the overall dietary iodine intake in the United States is considered adequate, the most recent NHANES (National Health and Nutrition Examination Survey) from 2007–2010 reports that the median urinary iodine concentration among pregnant U.S. women has dropped to <150 µg/L. This indicates mild iodine deficiency and highlights the risk of iodine deficiency reemergence in industrialized countries as salt intake decreases. These risks can be mitigated by the continued monitoring of iodine status, the adjustment of salt iodization levels, and the targeted supplementation of vulnerable subpopulations (promotion of iodine-containing prenatal vitamins).

**Clinical Manifestations**

If the deficiency of iodine is mild, thyroid enlargement does not become noticeable except when there is increased demand for the hormone during periods of rapid growth, as in adolescence and during pregnancy. In regions of moderate iodine deficiency, goiter observed in school children can disappear with maturity and reappear during pregnancy or lactation. Iodine-deficient goiters are more common in girls than in boys. In areas where iodine deficiency is severe, as in the hyperendemic highlands of Papua New Guinea, nearly half the population has large goiters, and endemic cretinism is common (Fig. 567-2).

![Figure 567-2 A 14 yr old boy with a large nodular goiter was seen in 2004, in an area of severe iodine-deficiency disorders in northern Morocco. He had tracheal and esophageal compression and hoarseness, probably as a result of damage to the recurrent laryngeal nerves. (From Zimmernamm MB, Jooste PL, Pandav CS: Iodine-deficiency disorders, Lancet 372:1251–1262, 2008, Fig 2.)](image-url)
Bibliography
Serum $T_4$ levels are often low in persons with endemic goiter, although clinical hypothyroidism is rare. This is true in New Guinea, the Congo, the Himalayas, and South America. Despite low serum $T_4$ levels, serum TSH concentrations are often normal or only moderately increased. In such patients, circulating levels of $T_4$ are elevated. Moreover, $T_4$ levels are also elevated in patients with normal $T_4$ levels, indicating a preferential secretion of $T_4$ by the thyroid in this disease and an adaptive increase in peripheral $T_4$ to $T_3$ conversion.

**Endemic cretinism** is the most serious consequence of iodine deficiency; it occurs only in geographic association with endemic goiter. The term *endemic cretinism* includes 2 different but overlapping syndromes: a **neurologic type** and a **myxedematous type**. The incidence of the 2 types varies among different populations. In Papua New Guinea, the neurologic type occurs almost exclusively, whereas in the Congo, the myxedematous type predominates. Both types are found in all endemic areas, and some persons have intermediate or mixed features.

The **neurologic syndrome** is characterized by intellectual disability, deaf-mutism, disturbances in standing and gait, and pyramidal signs such as clonus of the foot, the Babinski sign, and patellar hyperreflexia. Affected persons are goitrous but euthyroid, have normal pubertal development and adult stature, and have little or no impaired thyroid function. Persons with the **myxedematous syndrome** also are intellectually challenged and deaf and have neurologic symptoms, but in contrast to the neurologic type, they have delayed growth and sexual development, myxedema, and absence of goiter. Serum $T_4$ levels are low and TSH levels are markedly elevated. Delayed skeletal maturation may extend into the 3rd decade or later. Ultrasonographic examination shows thyroid atrophy.

**PATHOGENESIS**

The pathogenesis of the neurologic syndrome is attributed to iodine deficiency and hypothyroxinemia during pregnancy, leading to fetal and postnatal hypothyroidism. Although some investigators have attributed brain damage to a direct effect of elemental iodine deficiency in the fetus, most believe the neurologic symptoms are caused by combined fetal and maternal hypothyroxinemia. There is evidence for the presence of thyroid hormone receptors in the fetal brain as early as 7 wk of gestation. Although the normal fetal thyroid gland does not begin to produce significant amounts of thyroid hormone until midgestation, there is measurable $T_4$ in the coelomic fluid as early as 6 wk, almost certainly of maternal origin. These lines of evidence support a role for maternal thyroid hormone in fetal brain development in the 1st trimester. In addition, there is evidence of transplacental passage of maternal thyroid hormone into the fetus, which normally might ameliorate the effects of fetal hypothyroidism on the developing nervous system in the second half of pregnancy. Thus, iodine deficiency in the mother affects fetal brain development both in the 1st trimester and throughout pregnancy. Intake of iodine after birth is often sufficient for normal or only minimally impaired thyroid function.

The pathogenesis of the myxedematous syndrome leading to thyroid atrophy is more bewildering. Searches for additional environmental factors that might provoke continuing postnatal hypothyroidism have led to incrimination of selenium deficiency, goitrogenic foods, thiocyanates, and *Yersinia* (Table 567-1). Studies from western China suggest that thyroid autoimmunity might play a role. Children with myxedematous cretinism with thyroid atrophy, but not children with euthyroid cretinism, were found to have thyroid growth-blocking immunoglobulins of the kind found in infants with sporadic congenital hypothyroidism. Others are skeptical about any role of thyroid growth-blocking immunoglobulins to explain these findings.

**TREATMENT**

In many developing countries, administration of a single intramuscular injection of iodinated poppy seed oil to women prevents iodine deficiency during future pregnancies for approximately 5 yr. This form of therapy given to children younger than 4 yr of age with myxedematous cretinism results in a euthyroid state in 5 mo. Older children respond poorly and adults not at all to iodized oil injections, indicating an inability of the thyroid gland to synthesize hormone; these patients require treatment with $T_4$. Through the efforts of the World Health Organization and its program of universal salt iodization, the number of households worldwide with access to adequately iodized salt has increased from <10% in 1990 to 70% in 2012. In the Xinjiang province of China, where the usual methods of iodine supplementation had failed, iodination of irrigation water has increased iodine levels in soil, animals, and human beings. In other countries, iodinated salt in school meal programs gives children the dietary iodine they need. Still, political, economic, and practical obstacles have limited penetration of iodized food into regular diets around the world.

**NUTRIENTS**

| Selenium deficiency | Accumulated peroxides can damage the thyroid, and deiodinase deficiency impairs thyroid hormone activation |
| Iron deficiency | Reduces heme-dependent thyroperoxidase activity in the thyroid and might blunt the efficacy of iodine prophylaxis |
| Vitamin A deficiency | Increases TSH stimulation and goiter through decreased vitamin A–mediated suppression of the pituitary TSH-$eta$ gene |

TSH, thyroid-stimulating hormone.

**567.4 Acquired Goiter**

Stephen A. Huang and Stephen H. LaFranchi

Most acquired goiters are sporadic and develop from a variety of causes; patients are usually euthyroid but may be hypothyroid or hyperthyroid. The most common cause of acquired goiter is...
Bibliography

lymphocytic thyroiditis (see Chapter 566). Rarer causes in children include painless sporadic thyroiditis and subacute painful thyroiditis (de Quervain disease; see Chapter 566). Other causes include excess iodide ingestion and certain drugs, including amiodarone and lithium. Intrinsic biochemical defects in the synthesis of thyroid hormone are almost always associated with goiter; thyromegaly from milder defects occurs later in childhood. The occurrence of the disorder in siblings, onset in early life, and possible association with hypothyroidism (goitrous hypothyroidism) are important clues to the diagnosis.

**IODIDE GOITER**
A small percentage of patients treated with iodide preparations for prolonged periods acquire goiters. Iodides are commonly included for their expectorant effect in cough medicines and in proprietary mixtures for asthma. Goiters resulting from iodide administration are firm and diffusely enlarged, and in some instances hypothyroidism develops. In normal persons, acute administration of large doses of iodide inhibits the organification of iodine and the synthesis of thyroid hormone (Wolff-Chaikoff effect). This effect is short-lived and does not lead to permanent hypothyroidism. When iodide administration continues, an autoregulatory mechanism in normal persons limits iodide trapping and permits the level of iodide in the thyroid to decrease and organification to proceed normally. In patients with iodide-induced goiter, this escape does not occur, because of an underlying abnormality of biosynthesis of thyroid hormone. The persons most susceptible to the development of iodide goiter are those with lymphocytic thyroiditis or with a subclinical inborn error in thyroid hormone synthesis and those who have had a partial thyroidectomy.

Lithium carbonate, which is used to treat bipolar disorder, also causes goiters and mild hypothyroidism. Lithium decreases T4 and T3 synthesis and release; the mechanism producing the goiter or hypothyroidism is similar to that described for iodide goiter. Lithium and iodide also act synergistically to produce goiter; their combined use should be avoided.

Amiodarone, a drug used to treat cardiac arrhythmias, can cause thyroid dysfunction with goiter because it is rich in iodine. It is also a potent inhibitor of 5'-deiodinase, preventing conversion of T4 to T3. It can cause hypothyroidism, particularly in patients with underlying autoimmune disease. In other patients, it can cause thyrotoxicosis through either transient thyroiditis or the Jod-Basedow effect.

**SIMPLE GOITER (COLLOID GOITER)**
A few children with euthyroid goiters have simple goiters, a condition of unknown cause not associated with hypothyroidism or hyperthyroidism and not caused by inflammation or neoplasia. The condition predominates in girls and has a peak incidence before and during the pubertal years. Histologic examination of the thyroid either is normal or reveals variable follicular size, dense colloid, and flattened epithelium. The goiter may be small or large. It is firm in half the patients and occasionally is asymmetric or nodular. Levels of TSH are normal or low, scintiscans are normal, and thyroid antibodies are absent. Differentiation from lymphocytic thyroiditis might not be possible without a biopsy, but biopsy is usually not indicated. Therapy with thyroid hormone can help prevent progression to a large multinodular goiter, although it is difficult to separate any treatment effects from the natural history, which is for the goiter to decrease in size. Patients should be reevaluated periodically, because some have antibody-negative lymphocytic thyroiditis and therefore are at risk for changes in thyroid function (see Chapter 566).

**MULTINODULAR GOITER**
Rarely, a firm goiter with a lobulated surface and single or multiple palpable nodules is encountered. Areas of cystic change, hemorrhage, and fibrosis may be present. The incidence of this condition has decreased markedly with the use of iodine-enriched salt. A mild goitrogenic stimulus, acting over a long time, is thought to be the cause. Ultrasonographic examination can reveal multiple nodules that are nonfunctioning on scintiscans. Thyroid studies are usually normal. Some children with chronic lymphocytic thyroiditis develop multinodular goiter; TSH may be elevated, and thyroid antibodies may be present.

Children can develop toxic multinodular goiter, characterized by a suppressed TSH and hyperthyroidism. The condition occurs in children with McCune-Albright syndrome (usually resulting in hyperthyroidism), with TSH receptor–activating mutations, and it has been described in 3 children (including 2 siblings) with digital anomalies and cystic kidney disease. If hypofunctioning nodules within a multinodular goiter grow to significant size (≥1 cm), fine-needle aspiration should be considered to rule out malignancy (see Chapter 569).

**TOXIC GOITER (HYPERTHYROIDISM)**
See Chapter 568.

Bibliography is available at Expert Consult.
Bibliography

Hyperthyroidism results from excessive secretion of thyroid hormone; during childhood, with few exceptions, it is caused by Graves disease (Table 568-1). Graves disease is an autoimmune disorder; production of thyroid-stimulating immunoglobulin that binds to and activates the G-protein–coupled thyroid-stimulating hormone (TSH) receptor results in diffuse toxic goiter. Other causes of hyperthyroidism include gain-of-function germline mutations in the TSH receptor, which are found in both familial (autosomal dominant) and sporadic cases of non–autoimmune hyperthyroidism. These patients, whose disease can appear in the neonatal period or in later childhood, have thyroid hyperplasia with goiter and suppressed levels of TSH. Different activating mutations have been identified in some cases of thyroid adenomas. Hyperthyroidism occurs in some patients with McCune-Albright syndrome as a result of an activating mutation of the α subunit of the G-protein; these patients tend to have a multinodular goiter. Other rare causes of thyrotoxicosis that have been observed in children include painless sporadic thyroiditis, subacute painful thyroiditis, acute suppurative thyroiditis, thyrotoxicosis factitia, TSH-secreting adenomas, and hyperfunctioning thyroid carcinoma.

Suppression of plasma TSH indicates that the hyperthyroidism is not pituitary in origin. Hyperthyroidism caused by inappropriate thyrotropin secretion is rare and, in most cases, is caused by dominant negative thyroid hormone receptor mutations and pituitary resistance to thyroid hormone. TSH-secreting pituitary tumors are extremely rare in the pediatric population. In infants born to mothers with Graves disease, hyperthyroidism is almost always a transitory phenomenon; classic Graves disease during the neonatal period is rare. Choriocarcinoma, hydatidiform mole, and struma ovarii have caused hyperthyroidism in adults but have not been recognized as causes in children.

Studies have examined the health and quality of life of individuals with subclinical hyperthyroidism (i.e., with TSH <0.1 mU/L, but normal serum thyroxine [T₄] and triiodothyronine [T₃] concentrations) or who are euthyroid on antithyroid medication. These studies indicate that subclinical hyperthyroidism carries a risk of late-life atrial fibrillation, but no similar risks have been identified in the general pediatric population. There appears to be no difference in long-term quality of life among hyperthyroid patients treated with antithyroid medication, radioiodine ablation, or surgery. Quality of life was diminished relative to control persons in all 3 cases (see Chapter 568.1).

568.1 Graves Disease

Stephen A. Huang and Stephen H. LaFranchi

EPIDEMOIOLOGY

Graves disease occurs in approximately 0.02% of children (1:5,000). It has a peak incidence in the 11-15 yr old age group; there is a 5:1 female: male ratio. Most children with Graves disease have a positive family history of some form of autoimmune thyroid disease. In Japan, familial Graves disease, defined as Graves disease in a 1st-degree relative, occurs in 2-3% of cases.

ETIOLOGY

Enlargement of the thymus, splenomegaly, lymphadenopathy, infiltration of the thyroid gland and retroorbital tissues with lymphocytes and plasma cells, and peripheral lymphocytosis are well-established findings in Graves disease. In the thyroid gland, T-helper cells (CD4+) predominate in dense lymphoid aggregates; in areas of lower cell density, cytotoxic T cells (CD8+) predominate. The percentage of activated B lymphocytes infiltrating the thyroid is higher than in peripheral blood. A postulated failure of T-suppressor cells allows expression of T-helper cells, sensitized to the TSH antigen, which interact with B cells. These cells differentiate into plasma cells, which produce thyrotropin receptor–stimulating antibody (TRSAb). TRSAb binds to the receptor for TSH and stimulates cyclic adenosine monophosphate, resulting in thyroid hyperplasia and unregulated overproduction of thyroid hormone. In addition to TRSAb, thyrotropin receptor–blocking antibody (TRBAb), which binds but does not activate the TSH receptor, may also be produced, and the clinical course of the disease usually correlates with the ratio between the 2 antibodies.

The ophthalmopathy occurring in Graves disease appears to be caused by antibodies against antigens shared by the thyroid and eye muscle. TSH receptors have been identified in retroorbital adipocytes and might represent a target for antibodies. The antibodies that bind to the extraocular muscles and orbital fibroblasts stimulate the synthesis of glycosaminoglycans by orbital fibroblasts and produce cytotoxic effects on muscle cells.

In whites, Graves disease is associated with human leukocyte antigen (HLA)-B8 and HLA-DR3; the latter carries a 7-fold relative risk for Graves disease. Graves disease is also associated with other HLA-D3–related disorders, such as Addison disease, type 1 diabetes mellitus, myasthenia gravis, and celiac disease. Systemic lupus erythematosus, rheumatoid arthritis, vitiligo, idiopathic thrombocytopenic purpura, and pernicious anemia have been described in children with Graves disease. In family clusters, the conditions associated most commonly with Graves disease are autoimmune lymphocytic thyroiditis and hypothyroidism. In Japanese children, Graves disease is associated with different HLA haplotypes: HLA-DRB1*0405 and HLA-DQB1*0401. In the Chinese population, the RNASET2-FGFR1OP-CCR6 region at 6q27 and an intergenic region at 4p14 are important susceptibility loci.

CLINICAL MANIFESTATIONS

Approximately 5% of all patients with hyperthyroidism are younger than 15 yr of age; the peak incidence in these children occurs during adolescence. Although rare, Graves disease has begun between 6 wk and 2 yr of age in children born to mothers without a history of hyperthyroidism. The incidence is approximately 5 times higher in girls than in boys.

The clinical course in children is highly variable but usually is not so fulminant as in many adults (Table 568-2). Symptoms develop gradually; the usual interval between onset and diagnosis is 6-12 mo and may be longer in prepubertal children compared with adolescents. The earliest signs in children may be emotional disturbances accompanied by motor hyperactivity. The children become irritable and excitable, may be longer in prepubertal children compared with adolescents. The earliest signs in children may be emotional disturbances accompanied by motor hyperactivity. The children become irritable and excitable, and they cry easily because of emotional lability. They are restless sleepers and tend to kick their covers off. Their schoolwork suffers as a result of a short attention span and poor sleep. Tremor of the fingers can be
The Endocrine System

Table 568-2 Major Symptoms and Signs of Hyperthyroidism and of Graves Disease and Conditions Associated with Graves Disease

**MANIFESTATIONS OF HYPERTHYROIDISM**

**Symptoms**
- Hyperactivity, irritability, altered mood, insomnia, anxiety, poor concentration
- Heat intolerance, increased sweating
- Palpitations
- Fatigue, weakness
- Dyspnea
- Weight loss with increased appetite (weight gain in 10% of patients)
- Pruritus
- Increased stool frequency
- Thirst and polyuria
- Oligomenorrhea or amenorrhea

**Signs**
- Sinus tachycardia, atrial fibrillation (rare in children), supraventricular tachycardia
- Fine tremor, hyperkinesis, hyperreflexia
- Warm, moist skin
- Palmar erythema, onycholysis
- Hair loss or thinning
- Osteoporosis
- Muscle weakness and wasting
- High-output heart failure
- Chorea
- Periodic (hypokalemic) paralysis (primarily in Asian men)
- Psychosis (rare)

**MANIFESTATIONS OF GRAVES DISEASE**

- Diffuse goiter
- Ophthalmopathy
- A feeling of grittiness and discomfort in the eye
- Retrobulbar pressure or pain
- Eyelid lag or retraction
- Periorbital edema, chemosis, scleral or conjunctival injection
- Exophthalmos (proptosis)
- Extraocular muscle dysfunction
- Exposure keratitis
- Optic neuropathy
- Localized dermopathy (rare in children)
- Lymphoid hyperplasia
- Thyroid acropachy (rare in children)

**CONDITIONS ASSOCIATED WITH GRAVES DISEASE**

- Type 1 diabetes mellitus
- Addison disease
- Vitiligo
- Pernicious anemia
- Alopecia areata
- Myasthenia gravis
- Celiac disease

noticed if the arm is extended. There may be a voracious appetite combined with loss of or no increase in weight. Recent height measurements might show acceleration in growth velocity.

The size of the thyroid is variable. It may be so minimally enlarged that it initially escapes detection, but with careful examination, a diffuse goiter, soft with a smooth surface, is found in almost all patients. Exophthalmos is noticeable in most patients but is usually mild. Lagging of the upper eyelid as the eye looks downward, impairment of convergence, and retraction of the upper eyelid and infrequent blinking may be present (Figs. 568-1 and 568-2). Ocular manifestations can produce pain, lid erythema, chemosis, decreased extraocular muscle function, and decreased visual acuity (corneal or optic nerve involvement). The skin is smooth and flushed, with excessive sweating. Muscular weakness is uncommon but may be severe enough to result in clumsiness. Tachycardia, palpitations, dyspnea, and cardiac enlargement and insufficiency cause discomfort but rarely endanger the patient’s life. Atrial fibrillation is a rare complication. Mitral regurgitation, probably resulting from papillary muscle dysfunction, is the cause of the apical systolic murmur present in some patients. The systolic blood pressure and the pulse pressure are increased. Reflexes are brisk, especially the return phase of the Achilles reflex. Many of the findings in Graves disease result from hyperactivity of the sympathetic nervous system.

**Thyroid crisis, or thyroid storm,** is a form of hyperthyroidism manifested by a severe biochemical derangement, acute onset, hyperthermia, tachycardia, heart failure, and restlessness. There may be rapid progression to delirium, coma, and death. Precipitating events include trauma, infection, radioactive iodine treatment, or surgery. Apathetic
(or masked) hyperthyroidism is another variety of hyperthyroidism characterized by extreme listlessness, apathy, and cachexia. A combination of both forms can occur. These symptom complexes are rare in children.

**LABORATORY FINDINGS**

Levels of TSH are suppressed to below the lower range of normal. Serum levels of T3, free T3, and free T4 are typically elevated. In some patients, levels of T4 may be more elevated than those of T3. Antithyroid antibodies, including thyroid peroxidase antibodies, are often present. Most patients with newly diagnosed Graves disease have measurable TRSAb; the 2 methods to measure TRSAb are thyroid-stimulating immunoglobulin or thyrotropin-binding inhibitory immunoglobulin. Measurement of thyroid-stimulating immunoglobulin or thyrotropin-binding inhibitory immunoglobulin is useful in confirming the diagnosis of Graves disease. Children who experience an acceleration of growth might also have advanced skeletal maturation. Bone density may be reduced at diagnosis but returns to normal with treatment.

**DIFFERENTIAL DIAGNOSIS**

Diagnosis is rarely difficult once hyperthyroidism is considered. Elevated levels of T3, free T4, and TSH in association with suppressed levels of TSH are usually diagnostic (see Table 568-1). The combination of diffuse goiter and prolonged hyperthyroidism is nearly always caused by Graves disease, and the presence of characteristic eye or skin changes is diagnostic. Documentation of elevated TRSAb can confirm the diagnosis.

Other causes of hyperthyroidism are uncommon. In rare cases where clinical assessment cannot distinguish Graves hyperthyroidism from painless sporadic thyroiditis, 123I radioiodine uptake can be measured and used to determine the appropriateness of antithyroid medication. If a discrete thyroid nodule is palpated, a 123I scan should be performed to assess the possibility of a hyperfunctioning nodule(s). Some children with toxic multinodular goiter may have either a TSH receptor–activating mutation or McCune-Albright syndrome. If precocious puberty, polyostotic fibrous dysplasia, or café-au-lait pigmentation is present, the autonomous thyroid disorder of McCune-Albright syndrome is likely. Patients with generalized thyroid hormone resistance have elevated levels of free T3 and free T4, but levels of TSH are inappropriately elevated or normal. They must be differentiated from patients with TSH-secreting pituitary tumors who have elevated serum levels of the TSH α subunit. Most other causes of hyperthyroxinemia are uncommon but can result in erroneous diagnosis. Patients with elevated T4-binding globulin levels or familial dysalbuminemic hyperthyroxinemia have normal levels of free T3 and TSH. Rare patients with mutations in SLC16A2 (encoding the MCT8 thyroid hormone transporter) or THRHA (encoding thyroid hormone receptor α) can present with high serum T3 and inappropriately normal or high TSH but low serum T4 concentrations.

When hyperthyroxinemia is caused by exogenous thyroid hormone (thyrotoxicosis factitia), levels of free T4 and TSH are the same as those seen in Graves disease but, in contrast to Graves hyperthyroidism, serum thyroglobulin is very low, thyroid size is small, and 123I radioiodine uptake is suppressed.

**TREATMENT**

Most pediatric endocrinologists recommend initial medical therapy using antithyroid drugs rather than radioiodine or subtotal thyroidectomy, although radioiodine is gaining acceptance as initial treatment in children older than 10 yr of age. All therapeutic options have advantages and disadvantages (Table 568-3). The 2 antithyroid drugs used historically are propylthiouracil and methimazole (Tapazole). Both compounds inhibit incorporation of trapped inorganic iodide into organic compounds. However, there are important differences between the drugs. Methimazole is at least 10 times more potent than propylthiouracil on a weight basis and has a much longer serum half-life (6-8 hr vs 0.5 hr); propylthiouracil generally is administered 3 times daily, but methimazole can be given once daily. Unlike methimazole, propylthiouracil is heavily protein bound and has a lesser ability to cross the placenta and to pass into breast milk; theoretically, therefore, propylthiouracil is the preferred drug during pregnancy and for nursing mothers. Because of reports of severe liver disease in patients treated with propylthiouracil, with some patients requiring liver transplant or potentially suffering a fatal outcome, the consensus is to use only methimazole to treat children with Graves disease.

Adverse reactions occur with antithyroid drugs; most are mild, but some are life-threatening. Minor adverse effects occur in approximately 10–20%, and more-severe adverse effects occur in 2–5% of children. Reactions are unpredictable and can occur after therapy of any duration. Transient granulocytopenia (<2,000/mm3) is common; it is asymptomatic and is not a harbinger of agranulocytosis, and it usually is not a reason to discontinue treatment. Transient urticarial rashes are common. They may be managed by a short period off therapy, and then restarting the antithyroid drug. The most severe reactions are hypersensitive and include agranulocytosis (0.1–0.5%), hepatitis (0.2–1.0%), a lupus-like polyarthritis syndrome, glomerulonephritis, and an antineutrophilic cytoplasmic antibody–positive vasculitis involving the skin and other organs. Severe liver disease, including liver failure requiring transplantation, have been reported exclusively.

with propylthiouracil. The most common liver disease associated with methimazole is cholestatic jaundice, reversible when the drug is discontinued. Patients with severe adverse effects should be treated with radioiodine or thyroidectomy. In rare instances where hyperthyroidism is severe and methimazole cannot be used, a short course of propylthiouracil may be offered to restore euthyroidism prior to definitive therapy. Cases of congenital skin defects (aplasia cutis) have been seen in infants exposed in fetal life to methimazole, but this association does not appear to be a strong one.

The initial dosage of methimazole is 0.25-1.0 mg/kg/24 hr given once or twice daily. Smaller initial dosages should be used in early childhood. Careful surveillance is required after treatment is initiated. Rising serum levels of TSH to greater than normal indicates overtreatment and leads to increased size of the goiter. Clinical response becomes apparent in 3-6 wk, and adequate control is evident in 3-4 mo. The dose is decreased to the minimal level required to maintain a euthyroid state.

Most studies report a remission rate of approximately 25% after 2 yr of antithyroid drug treatment in children. Some studies find that longer treatment is associated with higher remission rates, with 1 study reporting a 50% remission rate after 4.5 yr of drug treatment. If a relapse occurs, it usually appears within 3 mo and almost always within 6 mo after therapy has been discontinued. Therapy may be resumed in case of relapse. Patients older than 13 yr of age, boys, those with a higher body mass index, and those with small goiters and modestly elevated T₃ levels appear to have earlier remissions.

A β-adrenergic blocking agent such as propranolol (0.5-2.0 mg/kg/24 hr orally, divided 3 times daily) or atenolol (1-2 mg/kg orally given once daily) is a useful supplement to antithyroid drugs in the management of severely toxic patients. Table 568-4 lists additional therapies for thyroid storm. Thyroid hormones potentiate the actions of catecholamines, including tachycardia, tremor, excessive sweating, lid lag, and stare. These symptoms abate with the use of propranolol, which does not, however, alter thyroid function or exophthalmos.

Radioiodine treatment or surgery is indicated when adequate cooperation for medical management is not possible, when an adequate trial of medical management has failed to result in permanent remission, or when severe side effects preclude further use of antithyroid drugs. Either of these treatments may also be preferred by the patient or parent.

### 568.2 Congenital Hyperthyroidism

**Stephen A. Huang and Stephen H. LaFranchi**

**ETIOLOGY AND PATHOGENESIS**

Neonatal Graves disease is caused by transplacental passage of TRSAb, but the clinical onset, severity, and course may be modified by the concurrent presence of thyrotropin receptor–blocking antibody and by the transplacental passage of antithyroid drugs taken by the mother. Very high levels of TRSAb usually result in classic neonatal hyperthyroidism, but if the infant has been exposed to antithyroid drugs, onset of symptoms is delayed by 3-4 days as the maternally derived antithyroid drug is metabolized. If thyrotropin receptor–blocking antibody is also present, onset of hyperthyroid symptoms may be delayed for several weeks. The mothers of these infants have active Graves disease. Graves disease in remission, a past history of Graves disease managed by radioactive iodine ablation or surgery, or rarely hypothyroidism and a history of lymphocytic thyroiditis.

Neonatal hyperthyroidism occurs in only approximately 2% of infants born to mothers with a history of Graves disease. Fetal tachycardia and goiter can give prenatal diagnosis and fetal ultrasound...
Bibliography
Occasionally, neonatal hyperthyroidism does not remit but persists into childhood. These patients can have an impressive family history of hyperthyroidism. Neonatal hyperthyroidism, without evidence for autoimmune disease in mother or infant, may be caused by a mutation in the \textit{TSHR} gene that produced constitutive activation of the receptor. Neonatal hyperthyroidism has also been reported in patients with McCune-Albright syndrome, a result of an activating mutation of the \( \alpha \) subunit of the G-protein. Under these circumstances, hyperthyroidism recurs when antithyroid drugs are discontinued; these children eventually must be treated with radioiodine or surgery.

**PROGNOSIS**

Advanced osseous maturation, microcephaly, and cognitive impairment occur when treatment is delayed. Intellectual development is normal in most treated infants with neonatal Graves disease, though some manifest neurocognitive problems from in utero hyperthyroidism. In some infants, in utero hyperthyroidism appears to suppress the hypothalamic-pituitary-thyroid feedback mechanism, and they develop permanent central hypothyroidism, requiring lifelong thyroid hormone treatment.

Bibliography

EPIDEMIOLOGY
Carcinoma of the thyroid is rare in childhood; the annual incidence in children younger than 15 yr of age is approximately 2 in 100,000 cases, compared with an annual incidence at all ages around the world of 4-10 in 100,000 cases. In the last 2 decades, the incidence in children has increased 2-fold. Compared to adults, childhood thyroid cancers are characterized by dramatically higher rates of metastasis and recurrence. Despite being widespread at discovery, pediatric thyroid cancers usually have an indolent course and, with adequate treatment, most patients have a favorable outcome.

PATHOGENESIS
At all ages, the vast majority of differentiated thyroid cancers are of follicular cell origin and, in North America, papillary carcinoma (88%) is the most common subtype. Interestingly, while their histologic features are similar, the thyroid cancers of childhood are genetically distinct from their adult counterparts. Although up to 70% of adults with papillary thyroid cancer exhibit pathogenic somatic mutations in BRAF or RAS, these mutations are extremely rare in children with papillary cancer. In contrast, RET-PTC translocations, which result in chimeric proteins containing the tyrosine kinase domains of RET fused to the regulatory sequences of ubiquitously expressed genes such as H1 and ELE1, are often found in childhood thyroid cancers. After papillary thyroid cancer, follicular cancer (10%) is the next most common type of childhood thyroid cancer. Medullary cancer (2%) and anaplastic thyroid cancers are relatively rare. Of note, only thyroid cancers of follicular cell origin (papillary and follicular carcinomas) respond to the adjunctive therapies of 131I therapy and thyroid-stimulating hormone (TSH) suppression.

Up to 10% of cases of follicular cell–derived thyroid cancers are familial, and these are usually inherited in an autosomal dominant manner. Familial syndromes associated with an increased risk of thyroid neoplasia include Cowden syndrome (characterized by mucocutaneous
lesions, breast cancer, macrocephaly, and endometrial tumors) and familial adenomatous polyposis. Germline mutations in the Dicer-1 gene have also been recognized as a cause of thyroid neoplasia. The evaluation of a child with thyroid nodule should include a medical and family history to assess for features of these syndromes.

The thyroid gland of children is unusually sensitive to exposure to external radiation. There probably is no threshold dose; 1 Gy results in a 7.7 relative risk of thyroid cancer. In the past, approximately 80% of children with cancer of the thyroid had received inappropriate therapeutic irradiation of the neck and adjacent areas during infancy for benign conditions such as “enlarged” thymus, hypertrophied tonsils and adenoids, hemangiomas, nevi, eczema, tinea capitis, and “cervical adenitis.” With the discontinuation of irradiation for benign conditions, this cause of thyroid cancer has vanished. The long-term survival of children who have received appropriate therapeutic irradiation of areas of the neck for neoplastic disease has made this cause of thyroid cancer and nodules increasingly prevalent; increased dose, younger age at time of treatment, and female sex are factors that increase the risk of thyroid cancer. Long-term risk data for cancer are sparse, but 15-50% of children who have received irradiation and chemotherapy for Hodgkin disease, leukemia, bone marrow transplantation, brain tumors, and other malignancies of the head and neck have elevated levels of TSH within the 1st yr of therapy, and 5-20% progress to hypothyroidism during the next 5-7 yr. Most large groups of treated children have a 10-30% incidence of benign thyroid nodules and an increased incidence of thyroid cancer. The latter begins to appear within 3-5 yr after radiation treatment and reaches a peak in 15-25 yr. It is unknown whether there is a period after which no more tumors develop. Administration of 131I for diagnostic or therapeutic purposes does not appear to increase the risk of thyroid cancer.

Thyroid cancer has been reported in children with congenital goiter or ectopic thyroid tissue. In these patients, and also in children with autoimmune thyroiditis and hypothyroidism, chronic TSH stimulation appears to play a pathogenic role. It is unclear if the course of thyroid cancer differs in these patients compared to the general population. From a practical standpoint, nodules that are detected in the context of these disorders should be fully evaluated for cancer risk as in other children.

**CLINICAL MANIFESTATIONS**

The incidence of childhood thyroid cancer peaks in adolescence and girls are more commonly affected than boys. A painless nodule in the thyroid or in the neck is the usual presentation of disease. Rapid growth and large nodule size, firmness, fixation to adjacent tissues, hoarseness, dysphagia, and neck lymphadenopathy should heighten the concern for thyroid cancer. Cervical lymph node metastasis is common, so any unexplained cervical lymph node enlargement warrants examination of the thyroid. The lungs are the most common site of distant metastasis. There may be no clinical manifestations referable to them and formal pulmonary function testing may be normal even with widespread macroscopic metastases. Radiologically, they appear as diffuse miliary or nodular infiltrations, typically greatest in the posterior basal portions. They may be mistaken for tuberculosis, histoplasmosis, or sarcoidosis. Other sites of metastasis include the mediastinum, axilla, long bones, skull, and brain. Almost all children are euthyroid, but rarely, the carcinoma is functional and produces symptoms of hyperthyroidism.

**DIAGNOSIS**

As detailed in the following section, patients usually present with a neck mass and virtually all have a thyroid nodule of significant size upon ultrasound. While several imaging features are significantly associated with thyroid cancer risk, none have sufficient negative predictive value to forgo tissue diagnosis. Papillary thyroid cancer is characterized by nuclear abnormalities that are well identified by cytology and fine-needle aspiration is the gold standard in the evaluation of adults with nodules. Growing literature supports its use in the pediatric population. In most cases, operative pathology is required to confirm the diagnosis of thyroid cancer and to stage the extent of disease.

**TREATMENT**

The primary therapy for thyroid cancer is surgical resection. Because intrathyroid spread is common in papillary thyroid, near-total thyroidec- tomy is the favored approach. Prior to this surgery, neck ultrasono- graphy should be performed to screen for sonographically abnormal lymph nodes. Suspicious lymph nodes may be biopsied preoperatively to determine the appropriateness and extent of initial lymph node dis- section. With the exception of very-low-risk patients, thyroidectomy is usually followed by adjunctive therapy with both TSH suppression (dosing levothyroxine to lower serum TSH and deprive residual thyroid cancer cells of this growth factor) and 131I therapy (to ablate the normal thyroid remnant and/or to treat residual thyroid cancer).

**PROGNOSIS**

Although extrathyroidal invasion and distant metastasis are more common in the pediatric population, most children with thyroid cancer have a good outcome. Families should be counseled that the response to 131I therapy is slow and that repeated treatments and years of care may be required to eliminate the disease. They should further be informed that many patients who are unable to achieve complete cure can be maintained in the well state with stable or slowly progressive cancer burden. For rare children with aggressive cancers that progress despite the optimization of conventional therapies, newer options, such as oral tyrosine kinase inhibitors, are available through research trials or on a compassionate basis. As with any cancer, psychosocial supports must be available, including access to social work and other mental health professionals.

Among solid tumors, thyroid cancer is unique in its capacity for late recurrence, sometimes occurring decades after initial presentation. For this reason, all children with thyroid cancer deserve lifelong monitoring for disease progression. For most patients, serum thyroglobulin is a sensitive and specific cancer marker. However, it must be recognized that about one fourth of patients have circulating antithyroglobulin autoantibodies that interfere with standard thyroglobulin assays and produce artifactualy low measurements. Because of this, antithyroglobulin autoantibodies must always be measured whenever serum thyroglobulin is assayed to confirm the latter’s reliability. As most thyroid cancer recurrences are local, surveillance should include serial neck ultrasonograms. Patients with higher recurrence risk or documentation of distant metastases typically benefit from additional anatomic imaging studies and from extended surveillance studies performed during TSH stimulation.

Bibliography is available at Expert Consult.

569.1 Solitary Thyroid Nodule

Stephen A. Huang and Stephen H. LaFranchi

The frequency of thyroid nodules increases with age. While sonographically detectable nodules are present in 19-67% of randomly selected adults, the estimated frequency of nodules in children is only 0.05-2.0%. Although early pediatric series cited extremely high rates of cancer in thyroid nodules (up to 70%), more recent studies of children report lower cancer prevalence (around 20-26%) that is similar to the 5-15% prevalence observed in adults. Thus, when a thyroid nodule is discovered in a child, parents should be counseled that the majority of nodules are benign.

Benign disorders that can occur as a solitary thyroid mass include benign adenomatous or colloid nodules, as well as a variety of congenital cysts (Table 569-1). A suddenly appearing or rapidly enlarging thyroid mass can indicate hemorrhage into a cyst or benign adenoma. When evaluating a child with a thyroid nodule, it is helpful to begin by measuring serum TSH.

In rare patients who present with a suppressed serum TSH, a thyroid scan, preferably using 131I or 123I-pertechnetate, should be performed to assess the possibility of a benign hyperfunctioning thyroid nodule. All other patients should proceed directly to ultrasound and, if a
Bibliography
Medullary thyroid carcinoma (MTC) arises from the parafollicular cells (C cells) of the thyroid and accounts for approximately 2% of thyroid malignancies in children. The majority of MTC cases are sporadic, but approximately 25% are familial, autosomal dominant disorders. Hereditary MTC is divided into 3 distinct syndromes: multiple endocrine neoplasia type 2A (MEN2A), multiple endocrine neoplasia type 2B (MEN2B), and familial MTC. In contrast to the somatic mutations associated with sporadic MTC, germline mutations in the RET protooncogene on chromosome 10q11.2 are inheritable and can cause familial medullary thyroid cancer at a later age. In young children, recommendations for the timing of prophylactic thyroidectomy are available for the common RET mutations. All children should be screened for pheochromocytoma before surgery. Monitoring the serum levels of calcitonin and carcinoembryonic antigen is useful in following the course of the disease after operation and in detecting metastatic lesions. Periodic screening for the development of pheochromocytoma and hyperparathyroidism is indicated. Metastases to the regional lymph nodes and to the liver can occur. Early clinical studies for thyroidectomy. No clinically recognizable manifestations are present. Peripheral neurofibromas and café-au-lait patches may be present, and intestinal ganglionomata is common. Diffuse proliferation of nerves and ganglion cells is found in mucosal, submucosal, myenteric, and subserosal plexus involving the small and large bowel as well as the esophagus. The patients may be tall, with arachnodactyly and a Marfan-like appearance. Scoliosis, pectus excavatum, pes cavus, and muscular hypotonia are common. The eyelids may be thickened and everted, the lips patulous and blubbery, the jaw prognathic. Feeding difficulties, poor sucking, diarrhea, constipation, and failure to thrive can begin in infancy or early childhood, many years before the appearance of neuromas or endocrine symptoms.

**TREATMENT**

Total thyroidectomy is indicated for all children who are shown by genetic studies to carry high-risk RET mutations. Recognition of familial forms of this tumor is critical to the early diagnosis and intervention in children at risk. MTC develops at an earlier age in patients with MEN2B and is more aggressive than in MEN2A. MTC has been seen in a 6 mo old child with MEN2B and in a 3 yr old child with MEN2A. In MEN2A, there is genotype–phenotype correlation between the specific mutation and the onset of C-cell hyperplasia or MTC. With codon 634 mutations, MTC occurs at an early age, whereas with mutations at codons 618, 620, and 804, MTC tends to occur at a later age. In young children, recommendations for the timing of prophylactic thyroidectomy are available for the common RET mutations. All these children should be screened for pheochromocytoma before surgery. Monitoring the serum levels of calcitonin and carcinoembryonic antigen is useful in following the course of the disease after operation and in detecting metastatic lesions. Periodic screening for the development of pheochromocytoma and hyperparathyroidism is indicated. Metastases to the regional lymph nodes and to the liver can occur. Early clinical studies support that prophylactic thyroidectomy is effective in preventing death from MTC.

Bibliography

Parathyroid hormone (PTH) and vitamin D are the principal regulators of calcium homeostasis (see Chapters 48 and 694). Calcitonin and PTH-related peptide (PTHrP) are important primarily in the fetus.

**PARATHYROID HORMONE**

PTH is an 84-amino-acid chain (95 kDa), but its biologic activity resides in the first 34 residues. In the parathyroid gland, a pro-pre-PTH (115-amino-acid chain) and a pro-PTH (90 amino acids) are synthesized. Pre-pro-PTH is converted to pro-PTH and pro-PTH to PTH. PTH (consisting of amino acids 1-84) is the major secretory product of the gland, but it is rapidly cleaved in the liver and kidney into smaller COOH-terminal, mid-region, and NH2-terminal fragments.

The occurrence of these fragments in serum has led to the development of a variety of assays. The 1-34 aminoterminal (N-terminus) fragments possess biologic activity but are present in low amounts in the circulation; assay of these fragments is most useful for detecting acute secretory changes. The carboxyterminal (C-terminus) and midregion fragments, although biologically inert, are cleared more slowly from the circulation and represent 80% of plasma immuno reactive PTH; concentrations of the C-terminal fragment are 50-500 times the level of the active hormone. The C-terminal assays are effective in detecting hyperparathyroidism, but because C-terminal fragments are removed from the circulation by glomerular filtration, these assays are less useful for evaluating the secondary hyperparathyroidism characteristic of renal disease. Only certain sensitive radioimmunoassays for PTH can differentiate the subnormal concentrations that occur in hypoparathyroidism from normal levels.

When serum levels of calcium fall, the signal is transduced through the calcium-sensing receptor, and secretion of PTH increases (Fig. 570-1). PTH stimulates activity of 1α-hydroxylase in the kidney, enhancing production of 1,25-dihydroxycholecalciferol, also written as 1,25(OH)2D3. The increased level of 1,25(OH)2D3 induces synthesis of a calcium-binding protein (calbindin-D) in the intestinal mucosa, with resultant absorption of calcium. PTH also mobilizes calcium by directly enhancing bone resorption, an effect that requires 1,25(OH)2D3. The resultant absorption of calcium increases the calcium-sensing receptor, hypocalcemia induces increased secretion of PTH and hypercalcemia depresses PTH secretion. Loss-of-function mutations cause an increased set point with respect to serum calcium, resulting in hypercalcemia and in the conditions of familial hypercalcemia (hyperparathyroidism and neonatal severe hyperparathyroidism). Acquired hypocalcemic hyperparathyroidism may be a result of autoantibodies to the calcium-sensing receptor and manifests with hypercalcemia and hyperparathyroidism. Gain-of-function mutations result in depressed secretion of PTH in response to hypocalcemia, leading to the syndrome of familial hypocalcemia with hypercalcuria (see Fig. 570-1).

**PARATHYROID HORMONE–RELATED PEPTIDE**

PTHrP is homologous to PTH only in the first 13 amino acids of its amino terminus, 8 of which are identical to PTH. Its gene is on the short arm of chromosome 12 and that of PTH is on the short arm of chromosome 11.

PTHrP, like PTH, activates PTH receptors in kidney and bone cells and increases urinary cyclic adenosine monophosphate and renal production of 1,25(OH)2D3. It is produced in almost every type of cell of the body, including every tissue of the embryo at some stage of development. PTHrP is critical for normal fetal development. Inactivating mutations of the receptor for PTH/PTHrP result in a lethal bone disorder characterized by short limbs and markedly advanced bone maturation known as Blomstrand chondrodysplasia (see Fig. 570-1). PTHrP appears to have a paracrine or autocrine role because serum levels are low except in a few clinical situations. Cord blood contains levels of PTHrP that are 3-fold higher than in serum from adults; it is produced by the fetal parathyroid glands and appears to be the main agent stimulating maternal-fetal calcium transfer. PTHrP appears to be essential for normal skeletal maturation of the fetus, which requires 30 g of calcium during a normal gestation. During pregnancy, maternal absorption of calcium increases from about 150 mg daily to 400 mg during the 2nd trimester.

As in cord blood, PTHrP levels are increased during lactation and in patients with benign breast hypertrophy. Breast milk and pasteurized bovine milk have levels of PTHrP that are 10,000 times higher than those of normal plasma. Most instances of the hormonal hypercalcemia syndrome of malignancy are caused by elevated concentrations of PTHrP.

**VITAMIN D**

See Chapter 51.

**CALCITONIN**

Calcitonin is a 32-amino-acid polypeptide. Its gene is on chromosome 11p and is tightly linked to that of PTH. The gene for calcitonin encodes 3 peptides: calcitonin, a 21-amino-acid carboxyterminal flanking peptide (katacalcin), and a calcitonin gene–related peptide. Katacalcin and calcitonin are cosecreted in equimolar amounts by the parafollicular cells (C cells) of the thyroid gland. Calcitonin appears to be of little consequence in children and adults because very high levels in patients with medullary carcinoma of the thyroid (a tumor arising from the C cells) do not cause hypercalcemia. In the fetus, however, circulating levels are high and appear to augment bone metabolism and skeletal growth; these high levels are probably stimulated by the normally high fetal calcium levels. Unlike the high levels in cord blood and circulating concentrations in young children, levels in older children and adults are low. Infants and children with congenital hypothyroidism (and presumed deficiency of C cells) have lower levels of calcitonin than do normal children.

Its action appears to be independent of PTH and vitamin D. Its main biologic effect appears to be the inhibition of bone resorption by decreasing the number and activity of bone-resorbing osteoclasts. This action of calcitonin is the rationale for its use in treatment of Paget disease. Calcitonin is synthesized in other organs, such as the gastrointestinal tract, pancreas, brain, and pituitary. In these organs, calcitonin is thought to behave as a neurotransmitter to impose a local inhibitory effect on cell function.

*Disorders due to PTH deficiency.†Defect due to defect in the PTH/PTHrP receptor.‡Defect due to insensitivity to PTH caused by defects downstream of the PTH/PTHrP receptor.§Defect due to altered set point in the Ca++/PTH axis, associated with a gain-of-function mutation of the CaSR.

MELAS = mitochondrial encephalopathy, stroke-like episodes, and lactic acidosis.
KSS = Kearns Sayre syndrome (progressive external ophthalmoplegia, pigmentary retinopathy, heart block, and cardiomyopathy).
MTPDS = mitochondrial trifunctional protein deficiency syndrome.
HDR = hypoparathyroidism, deafness, and renal anomalies.
APECED = autoimmune polyendocrinopathy-candidosis-ectodermal dysplasia.

Figure 570-1 Some components involved in calcium homeostasis. The calcium-sensing receptor (CaSR) and PTH/PTHrP receptor mediate their effects through G-protein-coupled signaling pathways, which, in turn, activate the adenyl cyclase (AC) and phospholipase C (PLC) systems. (From Thakker RV: Genetic development in hypoparathyroidism, Lancet 357: 974–976, 2001.)
Chapter 571
Hypoparathyroidism
Daniel A. Doyle

ETIOLOGY
Hypocalcemia is common in neonates between 12 and 72 hr of life, especially in premature infants, in infants with asphyxia, and in infants of diabetic mothers (early neonatal hypocalcemia; see Chapter 106; Table 571-1 and Fig. 571-1). After the 2nd to 3rd day and during the 1st wk of life, the type of feeding also is a determinant of the level of serum calcium (late neonatal hypocalcemia). The role played by the parathyroid glands in these hypocalcemic infants remains to be clarified, although functional immaturity of the parathyroid glands is invoked as 1 pathogenetic factor. In a group of infants with transient idiopathic hypocalcemia (1-8 wk of age), serum levels of parathyroid hormone (PTH) are significantly lower than those in normal infants. It is possible that the functional immaturity is a manifestation of a delay in development of the enzymes that convert glandular PTH to secreted PTH; other mechanisms are possible.

APLASIA OR HYPOPLASIA OF THE PARATHYROID GLANDS
Aplasia or hypoplasia of the parathyroid glands is often associated with the DiGeorge/velocardiofacial syndrome (see Fig. 570-1). This syndrome occurs in 1 in 4,000 newborns. In 90% of patients, the condition is caused by a deletion of chromosome 22q11.2. Approximately 25%

HDR, hypoparathyroidism, sensorineural deafness, and renal anomaly; HRD, hypoparathyroidism, retardation, dysmorphism; MELAS, mitochondrial encephalomyopathy with lactic acidosis and stroke-like episode; PTH, parathyroid hormone.

of these patients inherit the chromosomal abnormality from a parent. Neonatal hypocalcemia occurs in 60% of affected patients, but it is transitory in the majority; hypocalcemia can recur or can have its onset later in life. Associated abnormalities of the third and fourth pharyngeal pouches are common; these include conotruncal defects of the heart in 25%, velopharyngeal insufficiency in 32%, cleft palate in 9%, renal anomalies in 35%, and aplasia of the thymus with severe immunodeficiency in 1%. This syndrome has also been reported in a small number of patients with a deletion of chromosome 10p13, in infants of diabetic mothers, and in infants born to mothers treated with retinoic acid for acne early in pregnancy.

**X-LINKED RECESSIVE HYPOPARATHYROIDISM**

Familial clusters of hypoparathyroidism with various patterns of transmission have been described. In 2 large North American pedigrees, this disorder appears to be transmitted by an X-linked recessive gene located on Xq26-q27. In these families, the onset of febrile seizures characteristically occurs in infants from 2 wk to 6 mo of age. The absence of parathyroid tissue after detailed examination of a boy with hypoparathyroidism, mutations of the PTH gene have been found.

**HYPOPARATHYROIDISM, SENSORINEURAL DEAFNESS, AND RENAL ANOMALY SYNDROME**

Hypoparathyroidism, sensorineural deafness, and renal anomaly occur owing to mutations of the GATA3 gene. The protein encoded by this gene is essential in the development of the parathyroids, auditory system, and kidneys. The GATA3 gene is located at chromosome 10p14 and is nonoverlapping with the DiGeorge critical region at 10p13 (see Fig. 570-1).

**SUPPRESSION OF NEONATAL PARATHYROID HORMONE SECRETION BECAUSE OF MATERNAL HYPERPARATHYROIDISM**

Neonatal PTH secretion can be suppressed by maternal hyperparathyroidism, resulting in transient hypocalcemia in the newborn infant. It appears that neonatal hypocalcemia results from suppression of the fetal parathyroid glands by exposure to elevated levels of calcium in maternal and hence fetal serum. Tetany usually develops within 3 wk but may be delayed by 1 mo or more if the infant is breastfed. Hypocalcemia can persist for weeks or months. When the cause of hypocalcemia in an infant is unknown, measurements of calcium, phosphorus, and PTH should be obtained from the mother. Most affected mothers are asymptomatic, and the cause of their hyperparathyroidism is usually a parathyroid adenoma.

**AUTOSOMAL DOMINANT HYPOPARATHYROIDISM**

Patients with autosomal dominant hypoparathyroidism have an activating (gain-of-function) mutation of the Ca2+-sensing receptor, forcing the receptor to an “on” state with subsequent depression of PTH secretion even during hypocalcemia. The patients have hypercal-
ciuria. The hypocalcemia is usually mild and might not require treat-
ment beyond childhood (see Fig. 570-1).

HYPOPARATHYROIDISM ASSOCIATED WITH MITOCHONDRIAL DISORDERS
Mitochondrial DNA mutations in Kearns-Sayre syndrome, MELAS (myopathy, encephalopathy, lactic acidosis, and stroke-like episodes) syndrome, and in mitochondrial trifunctional protein–deficiency syn-
drome are associated with hypoparathyroidism. A diagnosis of mito-
chondrial cytopathy should be considered in patients with unexplained symptoms, such as ophthalmoplegia, sensorineural hearing loss, cardiac conduction disturbances, and tetany (see Fig. 570-1).

SURGICAL HYPOPARATHYROIDISM
Removal or damage of the parathyroid glands can complicate thyroid-
ectomy. Hypoparathyroidism has developed even when the parathy-
roid glands have been identified and left undisturbed at the time of operation. This may be the result of interference with the blood supply or of postoperative edema and fibrosis. Symptoms of tetany can occur abruptly postoperatively and may be temporary or permanent. In some instances, symptoms develop insidiously and go undetected until months after thyroidectomy. Occasionally, the first evidence of surgical hypoparathyroidism may be the development of cataract. The status of parathyroid function should be carefully monitored in all patients undergoing thyroidectomy.

Deposition of iron pigment or of copper in the parathyroid glands (thalassemia, Wilson disease) can produce hypoparathyroidism.

AUTOIMMUNE HYPOPARATHYROIDISM
An autoimmune mechanism for hypoparathyroidism is strongly sug-
gested by the finding of parathyroid antibodies and by its frequent association with other autoimmune disorders or organ-specific antibi-
odies. Autoimmune hypoparathyroidism is often associated with Addison disease and chronic mucocutaneous candidiasis. The associa-
tion of at least 2 of these 3 conditions has been tentatively classified as autoimmune polyglandular disease type I. It is also known as auto-
immune polyendocrinopathy, candidiasis, and ectodermal dystrophy (APECED). This syndrome is inherited in an autosomal recessive fashion and is not related to any single human leukocyte antigen–
associated haplotype. One third of patients with this syndrome have all 3 components; 66% have only 2 of 3 conditions. The candidiasis almost always precedes the other disorders (70% of cases occur in children younger than 5 yr of age); the hypoparathyroidism (90% of cases occur after 3 yr of age) usually occurs before Addison disease (90% of cases occur after 6 yr of age). A variety of other disorders, including alopecia areata or totalis, malabsorption disorder, pernicious anemia, alope-
cia areata or totalis, hepatitis, and primary gonadal insufficiency may also be associated with those of hypoparathyroidism.

Permanent physical and mental deterioration occurs if initiation of treatment is long delayed.

Laboratory Findings
The serum calcium level is low (5-7 mg/dL), and the phosphorus level is elevated (7-12 mg/dL). Blood levels of ionized calcium (usually approximately 45% of the total) more nearly reflect physiologic ade-
quacy but also are low. The serum level of alkaline phosphatase is normal, but hypocalcemia appears after effective treatment of the hypoparathyroidism. Levels of PTH are low when measured by immunoassay. Radiographs of the bones occasionally reveal an increased density limited to the metaphyses, suggesting heavy metal poisoning, or an increased density of the lamina dura. Radiographs or CT scans of the skull can reveal calcifications in the basal ganglia. There is a prolongation of the QT interval on the electrocar-
diogram, which disappears when the hypocalcemia is corrected. The electroencephalogram usually reveals widespread slow activity; the tracing returns to normal after the serum calcium concentration has been within the normal range for a few weeks, unless irreversible brain damage has occurred or unless the parathyroid insufficiency is associated with epilepsy. When hypoparathyroidism occurs concur-
rently with Addison disease, the serum level of calcium may be normal, but hypocalcemia appears after effective treatment of the adrenal insufficiency.

Treatment
Emergency treatment of neonatal tetany consists of intravenous injec-
tions of 5-10 mL or 1-3 mg/kg of a 10% solution of calcium gluconate (elemental calcium 9.3 mg/mL) at the rate of 0.5-1.0 mL/min while the heart rate is monitored and a total dose not to exceed 20 mg of elemental calcium/kg. Additionally, 1,25-dihydroxycholecalciferol (calcitriol) should be given. The initial dosage is 0.25 µg/24 hr; the maintenance dosage ranges from 0.01-0.10 µg/kg/24 hr to a maximum of 1-2 µg/24 hr. Calcitriol has a short half-life and should be given in 2 equal divided doses; it has the advantages of rapid onset of effect (1-4 days) and rapid reversal of hypercalcemia after discontinuation in the
event of overdosage (calcium levels begin to fall in 3–4 days). Calcitriol is supplied as an oral solution.

An adequate intake of calcium should be ensured. Supplemental calcium can be given in the form of calcium gluconate or calcium glubionate to provide 800 mg of elemental calcium daily, but it is rarely essential. Foods with high phosphorus content such as milk, eggs, and cheese should be reduced in the diet.

Clinical evaluation of the patient and frequent determinations of the serum calcium levels are indicated in the early stages of treatment to determine the requirement for calcitriol or vitamin D$_2$. If hypercalcemia occurs, therapy should be discontinued and resumed at a lower dose after the serum calcium level has returned to normal. In long-standing cases of hypercalcemia, repair of cerebral and dental changes is not likely. Pigmentation, lowering of blood pressure, or weight loss can indicate adrenal insufficiency, which requires specific treatment. *Patients with autosomal dominant hypocalcemic hypercalciuria can develop nephrocalcinosis and renal impairment if treated with vitamin D.*

**Differential Diagnosis**

Magnesium deficiency must be considered in patients with unexplained hypocalcemia. Concentrations of serum magnesium <1.5 mg/dL (1.2 mEq/L) are usually abnormal. Familial hypomagnesemia with secondary hypocalcemia has been reported in approximately 50 patients, most of whom developed tetany and seizures at 2–6 wk of age. Administration of calcium is ineffective, but administration of magnesium promptly corrects both calcium and magnesium levels. Oral supplements of magnesium are necessary to maintain levels of magnesium in the normal range. Two genetic forms have been described. One is caused by an autosomal recessive gene on chromosome 9, resulting in a specific defect in absorption of magnesium. The other is caused by an autosomal dominant gene on chromosome 11q23, resulting in renal loss of magnesium.

Hypomagnesemia also occurs in malabsorption syndromes such as Crohn disease and cystic fibrosis. Patients with autoimmune polyglan- dular disease type I and hypoparathyroidism can also have concurrent steatorrhea and low magnesium levels. Therapy with aminoglycosides causes hypomagnesemia by increasing urinary losses. It is not clear how low levels of magnesium lead to hypocalcemia. Evidence suggests that hypomagnesemia impairs release of PTH and induces resistance to the effects of the hormone, but other mechanisms also may be operative.

Poisoning with inorganic phosphate leads to hypocalcemia and tetany. Infants administered large doses of inorganic phosphates, either as laxatives or as sodium phosphate enemas, had sudden onset of tetany, with serum calcium levels <5 mg/dL and markedly elevated levels of phosphate. Symptoms are quickly relieved by intravenous administration of calcium. The mechanism of the hypocalcemia is not clear (see Chapter 55.6).

Hypocalcemia can occur early in the course of treatment of acute lymphoblastic leukemia. Hypocalcemia is usually associated with hyperphosphatemia resulting from destruction of lymphoblasts.

Episodic symptomatic hypocalcemia occurs in the **Kenny-Caffey syndrome**, which is characterized by medullary stenosis of the long bones, short stature, delayed closure of the fontanel, delayed bone age, and eye abnormalities. Idiopathic hypoparathyroidism and abnormal PTH levels have been found. Autosomal dominant and autosomal recessive modes of inheritance have been reported. Mutations of the **TBCE** gene (1q 43-44) perturb microtubule organization in diseased cells.

Brown EM: The calcium-sensing receptor (CaR) and its disorders, Hormones (Athens) 1:10–21, 2002.
In contrast to the situation in hypoparathyroidism, in pseudohypoparathyroidism (PHP) the parathyroid glands are normal or hyperplastic and they can synthesize and secrete parathyroid hormone (PTH). Serum levels of immunoreactive PTH are elevated even when the patient is hypocalcemic and may be elevated when the patient is normocalcemic. Neither endogenous nor administered PTH raises the serum levels of calcium or lowers the levels of phosphorus. The genetic defects in the hormone receptor adenylate cyclase system are classified into various types depending on the phenotypic and biochemical findings.

**TYPE IA**
Type Ia accounts for the majority of patients with PHP. Affected patients have a genetic defect of the α subunit of the stimulatory guanine nucleotide-binding protein (G$_s$α). This coupling factor is required for PTH bound to cell surface receptors to activate cyclic adenosine monophosphate (cAMP). Heterogeneous mutations of the G$_s$α gene have been documented; the gene is located on chromosome 20q13.2. Deficiency of the G$_s$α subunit is a generalized cellular defect and accounts for the association of other endocrine disorders with type Ia PHP. The defect is inherited as an autosomal dominant trait, and the paucity of father-to-son transmissions is thought to be a result of decreased fertility in males.

Tetany is often the presenting sign. Affected children have a short, stocky build and a round face. Brachydactyly with dimpling of the dorsum of the hand is usually present. The 2nd metacarpal is involved least often. As a result, the index finger occasionally is longer than the middle finger. Likewise, the 2nd metatarsal is only rarely affected. There may be other skeletal abnormalities such as short and wide phalanges, bowing, exostoses, and thickening of the calvaria. These patients often have calcium deposits and metaplastic bone formation subcutaneously. Moderate degrees of cognitive impairment, calcification of the basal ganglia, and lenticular cataracts are common in patients whose disease is diagnosed late.

Some members of affected kindreds may have the usual anatomic stigmata of PHP, but serum levels of calcium and phosphorus are normal despite reduced G$_s$α activity; however, PTH levels may be slightly elevated. Such patients have been labeled as having pseudo-pseudohypoparathyroidism. Transition from normocalcemia to hypocalcemia often occurs with increasing age of the patient. These phenotypically similar but metabolically dissimilar patients may be in the same family and have the same mutations of G$_s$α protein. It is not known what other factors cause clinically overt hypocalcemia in some affected patients and not in others. There is some evidence to suggest that the G$_s$α mutation is paternally transmitted in pseudopseudohypoparathyroidism and maternally transmitted in patients with type Ia disease. The gene may be imprinted in a tissue-specific manner.

In addition to resistance to PTH, resistance to other G-protein-coupled receptors for thyroid-stimulating hormone (TSH), gonadotropins, and glucagon can result in various metabolic effects. Clinical hypothyroidism is uncommon, but basal levels of TSH are elevated.
and thyrotropin-releasing hormone–stimulated TSH responses are exaggerated. Moderately decreased levels of thyroxine and increased levels of TSH have been demonstrated by newborn thyroid-screening programs, leading to the detection of type Ia PHP in infancy. In adults, gonadal dysfunction is common, as manifested by sexual immaturity, amenorrhea, oligomenorrhea, and infertility. Each of these abnormalities can be related to deficient synthesis of cAMP secondary to a deficiency of Gαs, but it is not clear why resistance to other G-protein–dependent hormones (corticotropin, vasopressin) is much less affected.

Serum levels of calcium are low, and those of phosphorus and alkaline phosphatase are elevated. Clinical diagnosis can be confirmed by demonstration of a markedly attenuated response in urinary phosphate and cAMP after intravenous infusion of the synthetic 1-34 fragment of human PTH (teriparatide acetate). Definitive diagnosis is established by demonstration of the mutated G protein.

**Type Ia with Precocious Puberty**

Two boys have been reported with both type Ia PHP and gonadotropin-independent precocious puberty (see Chapter 562.7). They were found to have a temperature-sensitive mutation of the Gαs protein. Thus, at normal body temperature (37°C [98.6°F]), the Gαs is degraded, resulting in PHP, but in the cooler temperature of the testes (33°C [91.4°F]) the Gα mutation results in constitutive activation of the luteinizing hormone receptor and precocious puberty.

**TYPE IB**

Affected patients have normal levels of G protein activity and a normal phenotypic appearance. These patients have tissue-specific resistance to PTH but not to other hormones. Serum levels of calcium, phosphorus, and immunoreactive PTH are the same as those in patients with type Ia PHP. These patients also show no rise in cAMP in response to exogenous administration of PTH. Bioactive PTH is not increased. The pathophysiology of the disorder in this group of patients is caused by paternal uniparental isodisomy of chromosome 20q and resulting GNAS1 methylation. This, along with the loss of the maternal GNAS1 gene, leads to PTH resistance in the proximal renal tubules, which leads to impaired mineral ion homeostasis.

**ACRODYSOSTOSIS WITH HORMONE RESISTANCE**

Patients with acrodysostosis resemble those with PHP type Ia, but defects in the Gα subunit are not present. Instead, in 1 subgroup of patients there is a defect in the gene encoding PRKAR1A, the cAMP-dependent regulatory subunit of protein kinase A that confers resistance to multiple hormones, including PTH. Another subgroup has a defect in a phosphodiesterase gene Pde4d. This subgroup also carries the phenotype of PHP type Ia but rarely exhibits the hormone resistance.

Chapter 573

Hyperparathyroidism

Daniel A. Doyle

Excessive production of parathyroid hormone (PTH) can result from a primary defect of the parathyroid glands such as an adenoma or hyperplasia (primary hyperparathyroidism). More often, the increased production of PTH is compensatory, usually aimed at correcting hypocalcemic states of diverse origins (secondary hyperparathyroidism). In vitamin D–deficient rickets and the malabsorption syndromes, intestinal absorption of calcium is deficient but hypocalcemia and tetany may be averted by increased activity of the parathyroid glands. In pseudohyperparathyroidism, PTH levels are elevated because a mutation in the G\(\alpha\) protein interferes with response to PTH. Early in chronic renal disease, hyperphosphatemia results in a reciprocal fall in the calcium concentration with a consequent increase in PTH, but in advanced stages of renal failure, production of 1,25(OH)\(_2\)D\(_3\) is also decreased, leading to worsening hypocalcemia and further stimulation of PTH. In some instances, if stimulation of the parathyroid glands has been sufficiently intense and protracted, the glands continue to secrete increased levels of PTH for months or years after kidney transplantation, with resulting hypercalcemia.

ETIOLOGY

Childhood hyperparathyroidism is uncommon. Onset during childhood is usually the result of a single benign adenoma. It usually becomes manifested after 10 yr of age. There have been a number of kindreds in which multiple members have hyperparathyroidism transmitted in an autosomal dominant fashion. Most of the affected family members are adults, but children have been involved in approximately 30% of the pedigrees. Some affected patients in these families are asymptomatic, and disease is detected only by careful study. In other kindreds, hyperparathyroidism occurs as part of the constellation known as the multiple endocrine neoplasia (MEN) syndromes or of the hyperparathyroidism–jaw tumor syndrome.

Neonatal severe hyperparathyroidism is a rare disorder. Symptoms develop shortly after birth and consist of anorexia, irritability, lethargy, constipation, and failure to thrive. Radiographs reveal subperiosteal bone resorption, osteoporosis, and pathologic fractures. Symptoms may be mild, resolving without treatment, or can have a rapidly fatal course if diagnosis and treatment are delayed. Histologically, the parathyroid glands show diffuse hyperplasia. Affected siblings have been observed in some kindreds, and parental consanguinity has been reported in several kindreds. Most cases have occurred in kindreds with the clinical and biochemical features of familial hypocalciuric hypercalcemia. Infants with neonatal severe hyperparathyroidism may be homozygous or heterozygous for the mutation in the Ca\(^{2+}\)-sensing receptor gene, whereas most persons with 1 copy of this mutation exhibit autosomal dominant familial hypocalciuric hypercalcemia.

MEN type I is an autosomal dominant disorder characterized by hyperplasia or neoplasia of the endocrine pancreas (which secretes gastrin, insulin, pancreatic polypeptide, and occasionally glucagon), the anterior pituitary (which usually secretes prolactin), and the parathyroid glands. In most kindreds, hyperparathyroidism is usually the presenting manifestation, with a prevalence approaching 100% by 50 yr of age and occurring only rarely in children younger than 18 yr of age. With appropriate DNA probes, it is possible to detect carriers of the gene with 99% accuracy at birth, avoiding unnecessary biochemical screening programs.

The gene for MEN type I is on chromosome 11q13; it appears to function as a tumor-suppressor gene and follows the 2-hit hypothesis of tumor development. The first mutation (germinal) is inherited and is recessive to the dominant allele; this does not result in tumor formation. A second mutation (somatic) is required to eliminate the normal allele, which then leads to tumor formation.

Hyperparathyroidism–jaw tumor syndrome is an autosomal dominant disorder characterized by parathyroid adenomas and fibrous osseous jaw tumors. Affected patients can also have polycystic kidney disease, renal hamartomas, and Wilms tumor. Although the condition affects adults primarily, it has been diagnosed as early as age 10 yr.

MEN type II may also be associated with hyperparathyroidism (see Chapter 569.2).

Transient neonatal hyperparathyroidism has occurred in a few infants born to mothers with hypoparathyroidism (idiopathic or surgical) or with pseudohypoparathyroidism. In each case, the maternal disorder had been undiagnosed or inadequately treated during pregnancy. The cause of the condition is chronic intrauterine exposure to
hypocalcemia with resultant hyperplasia of the fetal parathyroid glands. In the newborn, manifestations involve the bones primarily, and healing occurs between 4 and 7 mo of age.

**CLINICAL MANIFESTATIONS**

At all ages, the clinical manifestations of hypercalcemia of any cause include muscle weakness, fatigue, headache, anorexia, abdominal pain, nausea, vomiting, constipation, polydipsia, polyuria, weight loss, and fever. When hypercalcemia is of long duration, calcium may be deposited in the renal parenchyma (nephrocalcinosis), with progressively diminished renal function. Renal calculi can develop and can cause renal colic and hematuria. Osseous changes can produce pain in the back or extremities, disturbances of gait, genu valgum, fractures, and tumors. Height can decrease from compression of vertebrae; the patient can become bedridden. Detection of completely asymptomatic patients is increasing with the advent of automated panel assays that include serum calcium determinations.

Abdominal pain is occasionally prominent and may be associated with acute pancreatitis. Parathyroid crisis can occur, manifested by serum calcium levels >15 mg/dL and progressive oliguria, azotemia, stupor, and coma. In infants, failure to thrive, poor feeding, and hypotonia are common.

Cognitive impairment, convulsions, and blindness can occur as sequelae of long-standing hypercalcemia. Psychiatric manifestations include depression, confusion, dementia, stupor, and psychosis.

**LABORATORY FINDINGS**

The serum calcium level is elevated; 39 of 45 children with adenomas had levels >12 mg/dL. The hypercalcemia is more severe in infants with parathyroid hyperplasia; concentrations ranging from 15-20 mg/dL are common, and values as high as 30 mg/dL have been reported. Even when the total serum calcium level is borderline or only slightly elevated, ionized calcium levels are often increased. The serum phosphorus level is reduced to approximately 3 mg/dL or less, and the level of serum magnesium is low. The urine can have a low and fixed specific gravity, and serum levels of nonprotein nitrogen and uric acid may be elevated. In patients with adenomas who have skeletal involvement, serum phosphatase levels are elevated, but in infants with hyperplasia the levels of alkaline phosphatase may be normal even when there is extensive involvement of bone.

Serum levels of intact PTH are elevated, especially in relation to the level of calcium. Calcitonin levels are normal. Acute hypercalcemia can stimulate calcitonin release, but with prolonged hypercalcemia, hypercalcitoni nemia does not occur.

The most consistent and characteristic radiographic finding is resorption of subperiosteal bone, best seen along the margins of the phalanges of the hands. In the skull, there may be gross trabeculation or a granular appearance resulting from focal rarefaction; the lamina dura may be absent. In more advanced disease, there may be generalized rarefaction, cysts, tumors, fractures, and deformities. Approximately 10% of patients have radiographic signs of rickets. Radiographs of the abdomen can reveal renal calculi or nephrocalcinosis.

**DIFFERENTIAL DIAGNOSIS**

Other causes of hypercalcemia can result in a similar clinical pattern and must be differentiated from hyperparathyroidism (Table 573-1 and Fig. 573-1). A low serum phosphorus level with hypercalcemia is characteristic of primary hyperparathyroidism; elevated levels of PTH are also diagnostic. With hypercalcemia of any cause except hyperparathyroidism and familial hypocalciuric hypercalcemia, PTH levels are suppressed. Pharmacologic doses of corticosteroids lower the serum calcium level to normal in patients with hypercalcemia from other causes but generally do not affect the calcium level in patients with hyperparathyroidism.

**TREATMENT**

Surgical exploration is indicated in all instances. All glands should be carefully inspected; if an adenoma is discovered, it should be removed; very few instances of carcinoma are known in children. Most neonates with severe hypercalcemia require total parathyroidectomy; less-severe hypercalcemia remits spontaneously in others. Still others have been treated successfully with bisphosphonates and calcimimetics. The patient should be carefully observed postoperatively for the development of hypocalcemia and tetany; intravenous administration of calcium gluconate may be required for a few days. The serum calcium level then gradually returns to normal, and, under ordinary

---

### Table 573-1: Causes of Hypercalcemia

#### I. Neonate/Infant

**A. Maternal Disorders**
1. Excessive vitamin D ingestion, hypoparathyroidism, pseudohypoparathyroidism

**B. Neonate/Infant**
1. Iatrogenic: excessive intake of calcium, vitamin D, vitamin A
2. Phosphate depletion
3. Subcutaneous fat necrosis
4. Williams-Beuren syndrome (del7q11.23/BAZ1B) (transient receptor potential; 3-channel defect)
5. Neonatal severe hyperparathyroidism (CaSR)
6. Metaphyseal chondrodysplasia, Muck-Jansen type (PTH1R)
7. Idiopathic infantile hypercalcemia (CYP24A1) (25-hydroxyvitamin D 24-hydroxylase)
8. Persistent parathyroid hormone–related protein
9. Lactase/disaccharidase deficiency (LCT)
10. Infantile hypophosphatasia (TNSALP)
11. Mucolipidosis type II (GNPTAB)
12. Blue diaper syndrome
13. Antenatal Bartter syndrome types 1 and 2 (SLC12A1, KCNJ1)
14. Distal renal tubular acidosis
15. IMAGe syndrome (CDKN1C)
16. Post bone marrow transplantation for osteopetrosis
17. Endocrinopathies: primary adrenal insufficiency, severe congenital hypothyroidism, hyperthyroidism

#### II. Hyperparathyroidism

**A. Sporadic**
1. Parathyroid hyperplasia, adenoma, carcinoma

**B. Familial**
1. Neonatal severe hyperparathyroidism (CaSR)
2. Multiple endocrine neoplasia, type I (MEN1)
3. Multiple endocrine neoplasia, type II A (RET)
4. Multiple endocrine neoplasia, type II B (RET)
5. Multiple endocrine neoplasia, type IV (CDKN1B)
6. McCune-Albright syndrome (GNAS)
7. Familial isolated hyperparathyroidism 1 (CDC73)
8. Familial isolated hyperparathyroidism 2 (jaw tumor syndrome) (CDC73)
9. Familial isolated hyperparathyroidism 3
10. Jansen metaphyseal dysplasia (PTH1R)

**C. Secondary/Tertiary**
1. Postrenal transplantation
2. Chronic hyperphosphatemia

#### III. Familial Hypocalciuric Hypercalcemia

**A. Familial Hypocalciuric Hypercalcemia I (CaSR)**
1. Loss-of-function mutations in CaSR
   - Monoallelic: familial benign hypercalcemia
   - Biallelic: neonatal severe hyperparathyroidism

**B. Familial Hypocalciuric Hypercalcemia II (GNA11)**

**C. Familial Hypocalciuric Hypercalcemia III, Oklahoma Variant (AP2S1)**

**D. CaSR-blocking autoantibodies**

#### IV. Excessive Calcium or Vitamin D

**A. Milk-Alkali Syndrome**

**B. Exogenous Ingestion of Calcium or Vitamin D or Topical Application of Vitamin D (calcitriol or analog)**

**C. Ectopic Production of Calcitriol Associated with Granulomatous Diseases (sarcoidosis, cat-scratch fever; tuberculosis, histoplasmosis, coccidioidomycosis, leprosy; human immunodeficiency virus; cytomegalovirus; chronic inflammatory bowel disease)**

**D. Neoplasia**
1. Primary bone tumors
2. Metastatic tumors with osteolysis
3. Lymphoma, leukemia
4. Dysgerminoma
5. Pheochromocytoma
6. Tumors secreting parathyroid hormone–related peptide, growth factors, cytokines, prostaglandins, osteoclast-activating factors
7. Williams-Beuren Syndrome (del7q11.23)

#### V. Immobilization

#### VI. Other Causes

**A. Drugs: Thiazides, Lithium, Vitamin A and Analogs, Calcium, Alkali, Antiestrogens, Aminophylline**

**B. Total Parenteral Nutrition**

**C. Endocrinopathies: Hyperthyroidism, Addison disease, Pheochromocytoma**

**D. Vasoactive Intestinal Polypeptide–Secreting Tumor**

**E. Acute or Chronic Renal Failure/Administration of Aluminum**

**F. Hypophosphatasia**

**G. Juvenile Rheumatoid Arthritis: Cytokine Mediated**

circumstances, a diet high in calcium and phosphorus must be maintained for only several months after operation.

CT, real-time ultrasonography, and subtraction scintigraphy using sestamibi/technetium-pertechnetate alone and in combination have proved effective in localizing a single adenoma vs diffuse hyperplasia in 50-90% of adults. Parathyroid surgeons often rely on intraoperative selective venous sampling with intraoperative assay of PTH for localizing and removing the source of increased PTH secretion.

PROGNOSIS

The prognosis is good if the disease is recognized early and there is appropriate surgical treatment. When extensive osseous lesions are present, deformities may be permanent. A search for other affected family members is indicated.

573.1 Other Causes of Hypercalcemia

Daniel A. Doyle

FAMILIAL HYPOCALCIURIC HYPERCALCENIA (FAMILIAL BENIGN HYPERCALCENIA)

Patients with familial hypocalciuric hypercalcemia are usually asymptomatic, and the hypercalcemia is identified by chance during routine investigation for other conditions. The parathyroid glands are normal, PTH levels are inappropriately normal, and subtotal parathyroidectomy does not correct the hypercalcemia. Serum levels of magnesium are high normal or mildly elevated. The ratio of calcium-to-creatinine clearance is usually decreased despite hypercalcemia.

The disorder is inherited in an autosomal dominant manner and is caused by a mutant gene on chromosome 3q2. Penetration is near 100%, and the disorder can be diagnosed early in childhood by serum and urinary calcium concentrations. Detection of other affected family members is important to avoid inappropriate parathyroid surgery. The defect is an inactivating mutation in the Ca\(^{2+}\)-sensing receptor gene. This G-protein-coupled receptor senses the level of free Ca\(^{2+}\) in the blood and triggers the pathway to increase extracellular Ca\(^{2+}\) in the face of hypocalcemia. This receptor functions in the parathyroid and kidney to regulate calcium homeostasis; inactivating mutations lead to an increased set point with respect to serum Ca\(^{2+}\), resulting in mild to moderate hypercalcemia in heterozygotes.

GRANULOMATOUS DISEASES

Hypercalcemia occurs in 30-50% of children with sarcoidosis and less often in patients with other granulomatous diseases such as tuberculosis. Levels of PTH are suppressed, and levels of 1,25(OH)\(_2\)D\(_3\) are elevated. The source of eopitic 1,25(OH)\(_2\)D\(_3\) is the activated macrophage, through stimulation by interferon-\(\alpha\) from T lymphocytes, which are present in abundance in granulomatous lesions. Unlike renal tubular cells, the 1x-hydroxylase in macrophages is unresponsive to homeostatic regulation. Oral administration of prednisone (2 mg/kg/24 hr) lowers serum levels of 1,25(OH)\(_2\)D\(_3\) to normal and corrects the hypercalcemia.

HYPERCALCENIA OF MALIGNANCY

Hypercalcemia often occurs in adults with a wide variety of solid tumors but is identified much less often in children. It has been reported in infants with malignant rhabdoid tumors of the kidney or congenital mesoblastic nephroma and in children with neuroblastoma, medulloblastoma, leukemia, Burkitt lymphoma, dysgerminoma, and rhabdomyosarcoma. Serum levels of PTH are rarely elevated. In most patients, the hypercalcemia associated with malignancy is caused by elevated levels of parathyroid hormone–related peptide and not PTH. Rarely, tumors produce 1,25(OH)\(_2\)D\(_3\) or PTH ectopically.

MISCELLANEOUS CAUSES OF HYPERCALCENIA

Hypercalcemia can occur in infants with subcutaneous fat necrosis. Levels of PTH are normal. In 1 infant, the level of 1,25(OH)\(_2\)D\(_3\) was elevated and biopsy of the skin lesion revealed granulomatous infiltration, suggesting that the mechanism of the hypercalcemia was akin to that seen in patients with other granulomatous disease. In another infant, although the level of 1,25(OH)\(_2\)D\(_3\) was normal, PTH was suppressed, suggesting the hypercalcemia was not related to PTH. Treatment with prednisone is effective.

Hypophosphatemia, especially the severe infantile form, is usually associated with mild to moderate hypercalcemia (see Chapter 705). Serum levels of phosphorus are normal, and those of alkaline phosphatase are subnormal. The bones exhibit rachitic-like lesions on radiographs. Urinary levels of phosphoenolpyruvate, inorganic pyrophosphate, and pyridoxal 5'-phosphate are elevated; each is a natural substrate to a tissue-nonspecific (liver, bone, kidney) alkaline phosphatase enzyme. Missense mutations of the tissue-nonspecific alkaline phosphatase enzyme gene result in an inactive enzyme in this autosomal recessive disorder.

Idiopathic hypercalcemia of infancy is manifested by failure to thrive and hypercalcemia during the 1st yr of life, followed by spontaneous remission. Serum levels of phosphorus and PTH are normal. The condition has been defined as resulting from increased absorption of calcium from decreased degradation of 1,25(OH)\(_2\)D\(_3\). Mutations in the CYP24A1 gene that encodes 25-hydroxyvitamin D 24-hydroxylase, the key enzyme in 1,25(OH)\(_2\)D\(_3\) degradation, cause excessive levels of the active vitamin D metabolite, which, in turn, causes hypercalcemia in a subset of infants who receive supplemental vitamin D. An excessive rise in the level of 1,25(OH)\(_2\)D\(_3\) in response to PTH administration has been reported years after the hypercalcemic phase. Approximately 10% of patients with Williams syndrome also inconsistently exhibit associated infantile hypercalcemia. The phenotype consists of feeding difficulties, slow growth, elfin facies (small mandible, prominent maxilla, upturned nose), renovascular disorders, and a gregarious “cocktail party” personality. Cardiac lesions include supravalvular aortic stenosis, peripheral pulmonic stenosis, aortic hypoplasia, coronary artery stenosis, and atrial or ventricular septal defects. Nephrocalcinosis can develop if hypercalcemia persists. The IQ score of 50-70 is curiously accompanied by enhanced quantity and quality of vocabulary, auditory memory, and social use of language. A contiguous gene deletion syndrome with a submicroscopic deletion at chromosome 7q11.23, which includes deletion of 1 elastin allele, occurs in 90% of patients and seems to account for the vascular problems. Definitive diagnosis can be established by specific fluorescence in situ hybridization. The hypercalcemia and central nervous system symptoms may be caused by deletion of adjacent genes. Hypercalce mia has been successfully controlled with either prednisone or calcitriol.

Hypervitaminosis D resulting in hypercalcemia from drinking milk that has been incorrectly fortified with excessive amounts of vitamin D has been reported. Not all patients with hypervitaminosis D develop hypercalcemia. Affected infants can manifest failure to thrive, nephro lithiasis, poor renal function, and osteosclerosis. Serum levels of 25(OH)D are a better indicator of hypervitaminosis D than levels of 1,25(OH)\(_2\)D\(_3\), because 25(OH)D has a longer half-life.

Prolonged immobilization can lead to hypercalcemia and occasionally to decreased renal function, hypertension, and encephalopathy. Children who have hypophosphatemic rickets and undergo surgery with subsequent long-term immobilization are at risk for hypercalcemia and should therefore have their vitamin D supplementation decreased or discontinued.

Jansen-type metaphyseal chondrodysplasia is a rare genetic disorder characterized by short-limited dwarfism and severe but asymptom atic hypercalcemia (see Chapter 704). Circulating levels of PTH and parathyroid hormone–related peptide are undetectable. These patients have an activating PTH–parathyroid hormone–related peptide receptor mutation that results in aberrant calcium homeostasis and abnormalities of the growth plate.

Part XXVI  ❖  The Endocrine System

Section 4

Disorders of the Adrenal Gland

Chapter 574

Physiology of the Adrenal Gland

574.1 Histology and Embryology

Perrin C. White

The adrenal gland is composed of 2 endocrine tissues: the medulla and the cortex. The chromaffin cells of the adrenal medulla are derived from neuroectoderm, whereas the cells of the adrenal cortex are derived from mesoderm. Mesodermal cells also contribute to the development of the gonads. The adrenal glands and gonads have certain common enzymes involved in steroid synthesis; an inborn error in steroidogenesis in one tissue can also be present in the other.

The adrenal cortex of the older child or adult consists of 3 zones: the zona glomerulosa, the outermost zone located immediately beneath the capsule; the zona fasciculata, the middle zone; and the zona reticularis, the innermost zone, lying next to the adrenal medulla. The zona fasciculata is the largest zone, constituting approximately 75% of the cortex; the zona glomerulosa constitutes approximately 15% and the zona reticularis approximately 10%. Glomerulosa cells are small, with a lower cytoplasmic: nuclear ratio, an intermediate number of lipid inclusions, and smaller nuclei containing more condensed chromatin than the cells of the other 2 zones. The cells of the zona fasciculata are large, with a high cytoplasmic: nuclear ratio and many lipid inclusions. The cells are arranged in irregular anastomosing cords. The cytoplasmic: nuclear ratio is intermediate, and the compact cytoplasm has relatively little lipid content.

The zona glomerulosa synthesizes aldosterone, the most potent natural mineralocorticoid in humans. The zona fasciculata produces cortisol, the most potent natural glucocorticoid in humans, and the zona fasciculata and zona reticularis synthesize the adrenal androgens.

The adrenal medulla consists mainly of neuroendocrine (chromaffin) cells and glial (sustentacular) cells with some connective tissue and vascular cells. Neuroendocrine cells are polyhedral, with abundant cytoplasm and small, pale-staining nuclei. Under the electron microscope, the cytoplasm contains many large secretory granules that contain catecholamines. Glial cells have less cytoplasm and more basophilic nuclei.

The primordium of the fetal adrenal gland can be recognized at 3-4 wk of gestation just cephalad to the developing mesonephros. At 5-6 wk, the gonadal ridge develops into the steroidogenic cells of the gonads and adrenal cortex; the adrenal and gonadal cells separate, the adrenal cells migrate retroperitoneally, and the gonadal cells migrate caudally. At 6-8 wk of gestation, the gland rapidly enlarges, the cells of the inner cortex differentiate to form the fetal zone, and the outer subcapsular rim remains as the definitive zone. The primordium of the adrenal cortex is invaded at this time by sympathetic neural elements that differentiate into the chromaffin cells capable of synthesizing and storing catecholamines. Catechol O-methyltransferase, which converts norepinephrine to epinephrine, is expressed later in gestation. By the end of the 8th wk of gestation, the encapsulated adrenal gland is associated with the upper pole of the kidney. By 8-10 wk of gestation, the cells of the fetal zone are capable of active steroidogenesis.

In the full-term infant, the combined weight of both adrenal glands is 7-9 g. At birth, the inner fetal cortex makes up approximately 80% of the gland and the outer “true” cortex, 20%. Within a few days the fetal cortex begins to involute, undergoing a 50% reduction by 1 mo of age. Conversely, the adrenal medulla is relatively small at birth and undergoes a proportionate increase in size over the 1st 6 mo after birth. By 1 yr, the adrenal glands each weigh <1 g. Adrenal growth thereafter results in adult adrenal glands reaching a combined weight of 8 g. The zonae fasciculata and glomerulosa are fully differentiated by about 3 yr of age. The zona reticularis is not fully developed until puberty.

Adrenocorticotropic hormone (ACTH) is essential for fetal adrenal growth and maturation; feedback regulation of ACTH by cortisol is apparently established by 8-10 wk of gestation. Additional factors important in fetal growth and steroidogenesis include placental chorionic gonadotropins and a number of peptide growth factors produced by the placenta and fetus.

Several transcription factors are critical for the development of the adrenal glands. The 3 transcription factors associated with adrenal hypoplasia in humans are steroidogenic factor-1 (SF-1; NR5A1), DAX-1 (dosage-sensitive sex reversal, adrenal hypoplasia congenita, X chromosome; NR0B1), and the GLI3 oncogene. Disruption of SF-1, encoded on chromosome 9q33, results in gonadal and often adrenal agenesis, absence of pituitary gonadotropes, and an underdeveloped ventral medial hypothalamus. In-frame deletions and frameshift and missense mutations of this gene are associated with 46,XXY ovarian insufficiency and 46,XY gonadal dysgenesis. Mutations in the DAX1 gene, encoded on Xp21, result in adrenal hypoplasia congenita and hypogonadotrophic hypogonadism (see Chapter 575). Mutations in GLI3 on chromosome 7p13 cause Pallister-Hall syndrome, other features of which include hypothalamic hamartoblastoma, hypopituitarism, imperforate anus, and postaxial polydactyly.

The postnatal adrenal cortex is not static but, in fact, is continually regenerated from a population of stem or progenitor cells under the adrenal capsule. These cells move radially inward (i.e., centripetally) and can differentiate into zona glomerulosa or fasciculata cells as needed in response to the appropriate trophic stimuli (see Chapter 574.3). Several signaling pathways, including sonic hedgehog and Wnt, regulate this process. Sonic hedgehog expression is restricted to the peripheral cortical cells that do not express high levels of steroidogenic genes but give rise to the underlying differentiated cells of the cortex. Wnt/β-catenin signaling maintains the undifferentiated state and adrenal fate of adrenocortical stem/progenitor cells, in part through induction of its target genes DAX1 and inhibin-α, respectively. Adrenal tumors can result from constitutive activation of the Wnt signaling pathway (see Chapter 579), whereas mutations of DAX1 lead to loss of the ability of the adrenal cortex to regenerate; this condition is termed adrenal hypoplasia congenita (see Chapter 575).

Bibliography is available at Expert Consult.

574.2 Adrenal Steroid Biosynthesis

Perrin C. White

Cholesterol is the starting substrate for all steroid biosynthesis (Fig. 574-1). Although adrenal cortex cells can synthesize cholesterol de novo from acetate, circulating plasma lipoproteins provide most of the cholesterol for adrenal cortex hormone formation. Receptors for both low-density lipoprotein and high-density lipoprotein cholesterol are expressed on the surface of adrenocortical cells; the receptor is termed scavenger receptor class B, type I. Patients with familial hypercholesterolemia who lack low-density lipoprotein receptors have unimpaired adrenal steroidogenesis, suggesting that high-density lipoprotein is the more important source of cholesterol. Cholesterol is stored as cholesteryl esters in vesicles and subsequently hydrolyzed by cholesteryl ester hydrolases to liberate free cholesterol for steroid hormone synthesis.
Bibliography
The rate-limiting step of adrenal steroidogenesis is importation of cholesterol across the mitochondrial outer and inner membrane. This requires several proteins, particularly the steroidogenic acute regulatory (StAR) protein. The steroidogenic acute regulatory protein has a very short half-life, and its synthesis is rapidly induced by trophic factors (corticotropin); thus, it is the main short-term (minutes to hours) regulator of steroid hormone biosynthesis.

At the mitochondrial inner membrane, the side chain of cholesterol is cleaved to yield pregnenolone. This is catalyzed by the cholesterol side-chain cleavage enzyme (cholesterol desmolase, side-chain cleavage enzyme, P450sc, CYP11A1; the last term is the current systematic nomenclature), a cytochrome P450 (CYP) enzyme. Like other P450s, this is a membrane-bound hemoprotein with a molecular mass of approximately 50 kDa. It accepts electrons from a nicotinamide adenine dinucleotide phosphate–dependent mitochondrial electron transport system consisting of 2 accessory proteins, adrenodoxin reductase (a flavoprotein) and adrenodoxin (a small protein containing nonheme iron). P450 enzymes use electrons and O₂ to hydroxylate the substrate and form H₂O. In the case of cholesterol side-chain cleavage, 3 successive oxidative reactions are performed to cleave the C20,22 carbon bond. Pregnenolone then diffuses out of mitochondria and enters the endoplasmic reticulum. The subsequent reactions that occur depend on the zone of the adrenal cortex.

**ZONA GLomerulosa**

In the zona glomerulosa, pregnenolone is converted to progesterone by 3β-hydroxysteroid dehydrogenase type 2, a nicotinamide adenine dinucleotide–positive–dependent enzyme of the short-chain dehydrogenase type. Progesterone is converted to 11-deoxycorticosterone by sterol 21-hydroxylase (P450c21, CYP21), which is another P450. Like other P450s in the endoplasmic reticulum, it uses an electron transport system with only 1 accessory protein, P450 oxidoreductase.

Deoxycorticosterone then reenters mitochondria and is converted to aldosterone by aldosterone synthase (P450aldo, CYP11B2), a P450 enzyme structurally related to cholesterol desmolase. Aldosterone synthase also carries out 3 successive oxidations: 11β-hydroxylation, 18-hydroxylation, and further oxidation of the 18-methyl carbon to an aldehyde.

**ZONA Fasciculata**

In the endoplasmic reticulum of the zona fasciculata, pregnenolone and progesterone are converted by 17α-hydroxylase (P450c17, CYP17) to 17-hydroxypregnenolone and 17-hydroxyprogesterone, respectively. This enzyme is not expressed in the zona glomerulosa, which consequently cannot synthesize 17-hydroxylated steroids. 17-Hydroxypregnenolone is converted to 17-hydroxyprogesterone and 11-deoxycortisol by the same 3β-hydroxysteroid and 21-hydroxylase enzymes, respectively, as are active in the zona glomerulosa. Thus, inherited disorders in these enzymes affect both aldosterone and cortisol synthesis (see Chapter 576). Finally, 11-deoxycortisol reenters mitochondria and is converted to cortisol by steroid 11β-hydroxylase (P450c11, CYP11B1). This enzyme is closely related to aldosterone synthase but has low 18-hydroxylation and nonexistent 18-oxidase activity. Thus, under normal circumstances the zona fasciculata cannot synthesize aldosterone.

**ZONA Reticularis**

In the zona reticularis and to some extent in the zona fasciculata, the 17-hydroxylase (CYP17) enzyme has an additional activity, cleavage of the 17,20 carbon–carbon bond. This converts 17-hydroxypregnenolone to dehydroepiandrosterone (DHEA). DHEA is converted to androstenedione by HSD3B. This may be further converted in other tissues to testosterone and estrogens.
The circadian rhythm of corticotropin release is probably induced by a corresponding circadian rhythm of hypothalamic CRH secretion, regulated by the suprachiasmatic nucleus with input from other areas of the brain. Cortisol exerts a negative feedback effect on the synthesis and secretion of ACTH, CRH, and AVP. ACTH inhibits its own secretion, a feedback effect mediated at the level of the hypothalamus. Thus the secretion of cortisol is a result of the interaction of the hypothalamus, pituitary, and adrenal glands and other neural stimuli.

ACTH acts through a specific G-protein–coupled receptor (also termed melanocortin receptor-2, encoded by the MC2R gene) to activate adenylate cyclase and increase levels of cyclic adenosine monophosphate. Cyclic adenosine monophosphate has short-term (minutes to hours) effects on cholesterol transport into mitochondria by increasing expression of steroidogenic acute regulatory protein. The long-term effects (hours to days) of ACTH stimulation are to increase the uptake of cholesterol and the expression of genes encoding the enzymes required to synthesize cortisol. These transcriptional effects occur at least in part through increased activity of protein kinase A, which phosphorylates several transcriptional regulatory factors. MC2R trafficking and signaling are dependent on the MC2R accessory protein (MRAP). Mutations in either MC2R or MRAP can cause familial glucocorticoid deficiency (see Chapter 575).

**REGULATION OF ALDOSTERONE SECRETION**

The rate of aldosterone synthesis, which is normally 100- to 1,000-fold less than that of cortisol synthesis, is regulated mainly by the renin–angiotensin system and by potassium levels, with ACTH having only a short-term effect. In response to decreased intravascular volume, renin is secreted by the juxtaglomerular apparatus of the kidney. Renin is a proteolytic enzyme that cleaves angiotensinogen (renin substrate), an α2-globulin produced by the liver, to yield the inactive decapeptide angiotensin I. Angiotensin-converting enzyme in the lungs and other tissues rapidly cleaves angiotensin I to the biologically active octapeptide angiotensin II. Cleavage of angiotensin II produces the heptapeptide angiotensin III. Angiotensins II and III are potent stimulators of aldosterone secretion; angiotensin II is a more potent vasopressor agent. Angiotensins II and III occupy a G-protein–coupled receptor activating phospholipase C. This protein hydrolyzes phosphatidylinositol bisphosphate to produce inositol triphosphate and diacylglycerol, which raise intracellular calcium levels and activate adenylate cyclase and increase levels of cyclic adenosine monophosphate. Cyclic adenosine monophosphate has short-term (minutes to hours) effects on cholesterol transport into mitochondria by increasing expression of steroidogenic acute regulatory protein. The long-term effects (hours to days) of ACTH stimulation are to increase the uptake of cholesterol and the expression of genes encoding the enzymes required to synthesize cortisol. These transcriptional effects occur at least in part through increased activity of protein kinase A, which phosphorylates several transcriptional regulatory factors. MC2R trafficking and signaling are dependent on the MC2R accessory protein (MRAP). Mutations in either MC2R or MRAP can cause familial glucocorticoid deficiency (see Chapter 575).
Bibliography
Bibliography
Steroid hormones act through several distinct receptors corresponding to the known biologic activities of the steroid hormones: glucocorticoid, mineralocorticoid, progestin, estrogen, and androgen. These receptors belong to a larger superfamily of nuclear transcription factors that include, among others, thyroid hormone and retinoic acid receptors. They have a common structure that includes a carboxyterminal ligand-binding domain and a midregion DNA-binding domain. The latter domain contains 2 zinc fingers, each of which consists of a loop of amino acids stabilized by 4 cysteine residues chelating a zinc ion.

Unliganded glucocorticoid and mineralocorticoid receptors are found mainly in the cytosol. Hormone molecules diffuse through the cell membrane and bind receptors, changing their conformation and causing them to be translocated to the nucleus, where they bind DNA at specific hormone-response elements. Bound receptors can recruit other transcriptional coregulatory factors to DNA.

Whereas different steroids can share bioactivities because of their ability to bind to the same receptor, a given steroid can exert diverse biologic effects in different tissues. The diversity of hormonal responses is determined by the different genes that are regulated by each hormone in different tissues. Additionally, different combinations of coregulators are expressed in different tissues, allowing each steroid hormone to have many different effects. Moreover, enzymes can increase or decrease the affinity of steroids for their receptors and thus modulate their activity. 11β-Hydroxysteroid dehydrogenase type 1 (HSD11B1) converts cortisone, which is not a ligand for the glucocorticoid receptor, to cortisol, which is an active glucocorticoid. This increases local glucocorticoid concentrations in several tissues, especially the liver, where glucocorticoids maintain hepatic glucose output (see Chapter 575.4). Overexpression of this enzyme in adipose tissue can predispose to development of obesity. Conversely, HSD11B2 oxidizes cortisol to cortisone, particularly in the kidney, preventing mineralocorticoid receptors from being occupied by high levels of cortisol (see Chapter 575.4).

Although corticosteroid receptors mainly act in the nucleus, some responses to both glucocorticoids and mineralocorticoids begin within minutes, an interval too short to be accounted for by increased gene transcription and protein synthesis. Such “nongenomic” effects can in some cases be mediated by cell membrane–associated isoforms of the classic glucocorticoid and mineralocorticoid receptors, which can couple to a variety of rapid intracellular signaling pathways such as G proteins. Direct interactions with other proteins, such as ion channels, have been documented as well, particularly in the nervous system.

**ACTIONS OF GLUCOCORTICOIDS**

Glucocorticoids are essential for survival. The term glucocorticoid refers to the glucose-regulating properties of these hormones. However, glucocorticoids have multiple effects on carbohydrate, lipid, and protein metabolism. They also regulate immune, circulatory, and renal function. They influence growth, development, bone metabolism, and central nervous system activity.

In stress situations, glucocorticoid secretion can increase up to 10-fold. This increase is believed to enhance survival through increased cardiac contractility, cardiac output, sensitivity to the pressor effects of catecholamines and other pressor hormones, work capacity of the skeletal muscles, and capacity to mobilize energy stores.

**Metabolic Effects**

The primary action of the glucocorticoids on carbohydrate metabolism is to increase glucose production by increasing hepatic gluconeogenesis. Glucocorticoids also increase cellular resistance to insulin, thereby decreasing entry of glucose into the cell. This inhibition of glucose uptake occurs in adipocytes, muscle cells, and fibroblasts. In addition to opposing insulin action, glucocorticoids can work in parallel with insulin to protect against long-term starvation by stimulating glycogen deposition and production in liver. Both hormones stimulate glycogen synthesize activity and decrease glycogen breakdown. Glucocorticoid excess can cause hyperglycemia, and glucocorticoid deficiency can cause hypoglycemia.

Glucocorticoids increase free fatty acid levels by enhancing lipolysis, decreasing cellular glucose uptake, and decreasing glycerol production, which is necessary for reesterification of fatty acids. This increase in lipolysis is also stimulated through the permissive enhancement of lipolytic action of other factors such as epinephrine. This action affects adipocytes differently according to their anatomic locations. In the patient with glucocorticoid excess, fat is lost in the extremities but it is increased in the trunk (centripetal obesity), neck, and face (moon facies). This may involve effects on adipocyte differentiation.

Glucocorticoids generally exert a catabolic or antiinflammatory effect on protein metabolism. Proteolysis in fat, skeletal muscle, bone, lymphoid, and connective tissue increases amino acid substrates that can be used in gluconeogenesis. Cardiac muscle and the diaphragm are almost entirely spared from this catabolic effect.

**Circulatory and Renal Effects**

Glucocorticoids have a positive inotropic influence on the heart, increasing the left ventricular work index. Moreover, they have a permissive effect on the actions of epinephrine and norepinephrine on both the heart and the blood vessels. In the absence of glucocorticoids, decreased cardiac output and shock can develop; in states of glucocorticoid excess, hypertension is often observed. This may be a result of activation of the mineralocorticoid receptor (see Chapter 575.4), which occurs when renal HSD11B2 is saturated by excessive levels of glucocorticoids.

**Growth**

In excess, glucocorticoids inhibit linear growth and skeletal maturation in children, apparently through direct effects on the epiphyses. However, glucocorticoids are also necessary for normal growth and development. In the fetus and neonate, they accelerate differentiation and development of various tissues, including the hepatic and gastrointestinal systems, as well as the production of surfactant in the fetal lung. Glucocorticoids are often given to pregnant women at risk for delivery of premature infants in an effort to accelerate these maturational processes (see Chapters 97.2 and 101.3).

**Immunologic Effects**

Glucocorticoids play a major role in immune regulation. They inhibit synthesis of glycolipids and prostaglandin precursors and the actions of bradykinin. They also block secretion and actions of histamine and proinflammatory cytokines (tumor necrosis factor-α, interleukin-1, and interleukin-6), thus diminishing inflammation. High doses of glucocorticoids deplete monocytes, eosinophils, and lymphocytes, especially T cells. They do so at least in part by inducing cell-cycle arrest in the G0 phase and by activating apoptosis through glucocorticoid receptor–mediated effects. The effects on lymphocytes are primarily exerted on T-helper 1 cells and hence on cellular immunity, whereas the T-helper 2 cells are spared, leading to a predominantly humoral immune response. Pharmacologic doses of glucocorticoids can also decrease the size of immunologic tissues (spleen, thymus, and lymph nodes).

Glucocorticoids increase circulating polymorphonuclear cell counts, mostly by preventing their egress from the circulation. Glucocorticoids decrease diapedesis, chemotaxis, and phagocytosis of polymorphonuclear cells. Thus, the mobility of these cells is altered such that they do not arrive at the site of inflammation to mount an appropriate immune response. High levels of glucocorticoids decrease inflammatory and cellular immune responses and increase susceptibility to certain bacterial, viral, fungal, and parasitic infections.

**Effects on Skin, Bone, and Calcium**

Glucocorticoids inhibit fibroblasts, leading to increased bruising and poor wound healing through cutaneous atrophy. This effect explains...
the thinning of the skin and striae that are seen in patients with Cushing syndrome.

Glucocorticoids have the overall effect of decreasing serum calcium and have been used in emergency therapy for certain types of hypercalcemia. This hypocalcemic effect probably results from a decrease in the intestinal absorption of calcium and a decrease in the renal reabsorption of calcium and phosphorus. Serum calcium levels, however, generally do not fall below normal because of a secondary increase in parathyroid hormone secretion.

The most significant effect of long-term glucocorticoid excess on calcium and bone metabolism is osteoporosis. Glucocorticoids inhibit osteoblastic activity by decreasing the number and activity of osteoblasts. Glucocorticoids also decrease osteoclastic activity but to a lesser extent, leading to low bone turnover with an overall negative balance. The tendency of glucocorticoids to lower serum calcium and phosphate levels causes secondary hyperparathyroidism. These actions decrease bone accretion and cause a net loss of bone mineral. Compliance with oral bisphosphonates, agents that are effective against glucocorticoid-induced osteoporosis, is poor, but evidence suggests that yearly treatment with intravenous zoledronic acid is just as effective.

Central Nervous System Effects

Glucocorticoids readily penetrate the blood–brain barrier and have direct effects on brain metabolism. They decrease certain types of central nervous system edema and are often used to treat increased intracranial pressure. They stimulate appetite and cause insomnia with a reduction in rapid eye movement sleep. There is an increase in irritability and emotional lability, with an impairment of memory and ability to concentrate. Mild to moderate glucocorticoid excess for a limited period often causes a feeling of euphoria or well-being, but glucocorticoid excess and deficiency can both be associated with clinical depression. Glucocorticoid excess produces psychosis in some patients.

Glucocorticoid effects in the brain are mediated largely through interactions with both the mineralocorticoid and glucocorticoid receptors (sometimes referred to in this context as type I and type II corticosteroid receptors, respectively). Activation of type II receptors increases sensitivity of hippocampal neurons to the neurotransmitter serotonin, which might help explain the euphoria associated with high doses of glucocorticoids. Glucocorticoids suppress release of CRH in the anterior hypothalamus, but they stimulate it in the central nucleus of the amygdala and lateral bed nucleus of the stria terminalis, where it can mediate fear and anxiety states. Glucocorticoids and other steroids might have nongenomic effects by modulating activities of both γ-aminobutyric acid and N-methyl-D-aspartate receptors.

ACTIONS OF MINERALOCORTICOIDS

The most important mineralocorticoids are aldosterone and, to a lesser degree, 11-deoxycorticosterone; corticosterone and cortisol are normally not important as mineralocorticoids unless secreted in excess. Mineralocorticoids have more limited actions than glucocorticoids. Their major function is to maintain intravascular volume by conserving sodium and eliminating potassium and hydrogen ions. They exert their major function in the kidney, gut, and salivary and sweat glands. Aldosterone can have distinct effects in other tissues. Mineralocorticoid receptors are found in the heart and vascular endothelium, and aldosterone increases myocardial fibrosis in heart failure.

Mineralocorticoids have their most important actions in the distal convoluted tubules and cortical collecting ducts of the kidney, where they induce reabsorption of sodium and secretion of potassium. In the medullary collecting duct, they act in a permissive fashion to allow vasopressin to increase osmotic water flux. Thus, patients with mineralocorticoid deficiency can develop weight loss, hypotension, hyponatremia, and hyperkalemia, whereas patients with mineralocorticoid excess can develop hypertension, hypokalemia, and metabolic alkalosis (see Chapters 575-578). The mechanisms by which aldosterone affects sodium excretion are incompletely understood. Most effects of aldosterone are presumably due to changes in gene expression mediated by the mineralocorticoid receptor, and indeed levels of subunits of both the Na⁺K⁺-adenosine triphosphatase and the epithelial sodium channel increase in response to aldosterone. Additionally, aldosterone increases expression of the serum and glucocorticoid-regulated kinase, which indirectly reduces turnover of epithelial sodium channel subunits and thus increases the number of open sodium channels.

The mineralocorticoid receptor has similar affinities in vitro for cortisol and aldosterone, yet cortisol is a weak mineralocorticoid in vivo. This discrepancy results from the action of HSD11B2, which converts cortisol to cortisone. Cortisone is not a ligand for the receptor, whereas aldosterone is not a substrate for the enzyme. Pharmacologic inhibition (as occurs with excessive consumption of licorice) or genetic deficiency of this enzyme allows cortisol to occupy renal mineralocorticoid receptors and produce sodium retention and hypertension; the genetic condition is termed apparent mineralocorticoid excess syndrome.

ACTIONS OF THE ADRENAL ANDROGENS

Many actions of adrenal androgens are exerted through their conversion to active androgens or estrogens such as testosterone, dihydrotestosterone, estrone, and estradiol. In men, <2% of the biologically important androgens are derived from adrenal production, whereas in women approximately 50% of androgens are of adrenal origin. The adrenal contribution to circulating estrogen levels is mainly important in pathologic conditions such as feminizing adrenal tumors. Adrenal androgens contribute to the physiologic development of pubic and axillary hair during normal puberty. They also play an important role in the pathophysiology of congenital adrenal hyperplasia, premature adrenarche, adrenal tumors, and Cushing syndrome (see Chapters 576, 577, and 579).

In humans, circulating levels of DHEA and DHEAS, the chief adrenal androgens, reach a peak in early adulthood and then decline. This has led to speculation that age-related physiologic changes might be reversed by DHEA administration, and beneficial effects have been suggested (but not proved) on insulin sensitivity, bone mineral density, muscle mass, cardiovascular risk, obesity, cancer risk, autoimmunity, and the central nervous system.

Synthetic Corticosteroids

Many synthetic analogs of cortisol and hydrocortisone are available. Prednisone and prednisolone are derivatives with an additional double bond in ring A. Like cortisone, prednisone is not an active steroid but it is converted to prednisolone by HSD11B1 in the liver. Prednisone and prednisolone are 4-5 times as potent in antiinflammatory and carbohydrate activity but have slightly less effect on retention of water and sodium than cortisol. Halogenated derivatives have different effects. Betamethasone and dexamethasone have 25-40 times the glucocorticoid potency of cortisol but have little mineralocorticoid effect. These analogs are usually used in pharmacologic doses for their anti-inflammatory or immunosuppressive properties. The antiinflammatory activity of fludrocortisone is about 15 times that of hydrocortisone, but fludrocortisone is more than 125 times as active a mineralocorticoid; it is used to treat aldosterone deficiency.

574.5 Adrenal Medulla

Perrin C. White

The principal hormones of the adrenal medulla are the physiologically active catecholamines: dopamine, norepinephrine, and epinephrine (Fig. 574-3). Catecholamine synthesis also occurs in the brain, in sympathetic nerve endings, and in chromaffin tissue outside the adrenal medulla. Metabolites of catecholamines are excreted in the urine, principally 3-methoxy-4-hydroxymandelic acid, metanephrine,
Bibliography
and normetanephrine. Urinary metanephrines and catecholamines are measured to detect pheochromocytomas of the adrenal medulla and sympathetic nervous system (see Chapter 580).

The proportions of epinephrine and norepinephrine in the adrenal gland vary with age. In early fetal stages, there is practically no epinephrine; at birth, norepinephrine remains predominant. However in adults, norepinephrine accounts for only 10-30% of the pressor amines in the medulla.

The effects of catecholamines are mediated through a series of G-protein-coupled adrenergic receptors. Both epinephrine and norepinephrine raise the mean arterial blood pressure, but only epinephrine increases cardiac output. By increasing peripheral vascular resistance, norepinephrine increases systolic and diastolic blood pressures with only a slight reduction in the pulse rate. Epinephrine increases the pulse rate and, by decreasing the peripheral vascular resistance, decreases the diastolic pressure. The hyperglycemic and calorigenic effects of norepinephrine are much less pronounced than are those of epinephrine.

Bibliography
In primary adrenal insufficiency, congenital or acquired lesions of the adrenal cortex prevent production of cortisol and often aldosterone (Table 575-1). Acquired primary adrenal insufficiency is termed Addison disease. Dysfunction of the anterior pituitary gland or hypothalamus can cause a deficiency of corticotropin (adrenocorticotropic hormone [ACTH]) and lead to hypofunction of the adrenal cortex, termed secondary adrenal insufficiency; the term tertiary adrenal insufficiency is sometimes used to denote cases arising from hypothalamic dysfunction (Table 575-2).

Primary adrenal insufficiency in children is most frequently caused by genetic conditions that are often but not always manifested in infancy and less often by acquired problems such as autoimmune conditions (Table 575-3). Susceptibility to autoimmune conditions often has a genetic basis, and so these distinctions are not absolute.

INHERITED ETIOLOGIES

Inborn Defects of Steroidogenesis

The most common causes of adrenocortical insufficiency in infancy are the salt-losing forms of congenital adrenal hyperplasia (see Chapter 576). Approximately 75% of infants with 21-hydroxylase deficiency, almost all infants with lipid adrenal hyperplasia, and most infants with a deficiency of 3β-hydroxysteroid dehydrogenase manifest salt-losing symptoms in the newborn period because they are unable to synthesize either cortisol or aldosterone.

Adrenal Hypoplasia Congenita

Adrenal hypoplasia congenita (AHC) is a relatively frequent cause of adrenal failure in boys along with congenital adrenal hyperplasia, autoimmune disease, and adrenoleukodystrophy. The name of the disorder notwithstanding, AHC is predominantly a failure of development of the definitive zone of the adrenal cortex; the fetal zone may be relatively normal. Consequently, adrenal insufficiency generally becomes evident as the fetal zone involutes postnatally (see Chapter 574), with onset in infancy or in the 1st 2 yr of life, but occasionally in later childhood or even adulthood. In some cases, aldosterone deficiency becomes evident before cortisol deficiency.

The disorder is caused by mutation of the \( \text{DAX1} \) (\( \text{NR0B1} \)) gene, a member of the nuclear hormone receptor family, located on Xp21. Boys with AHC often do not undergo puberty owing to hypogonadotropic hypogonadism caused by the same mutated \( \text{DAX1} \) gene. Cryptorchidism, sometimes noted in these boys, is probably an early manifestation of hypogonadotropic hypogonadism, but often testicular function in infants is normal, with a typical or even an unusually prolonged testosterone surge in the 1st mo of life.

AHC occasionally occurs as part of a contiguous gene deletion syndrome together with Duchenne muscular dystrophy, glycerol kinase deficiency, cognitive impairment, or a combination of these conditions.

Other Genetic Causes of Adrenal Hypoplasia

The transcription factor SF-1 is required for adrenal and gonadal development (see Chapter 574). Males with a heterozygous mutation in SF-1 (\( \text{NR5A1} \)) have impaired development of the testes despite the presence of a normal copy of the gene on the other chromosome and can appear to be female, similar to patients with lipoid adrenal hyperplasia (see Chapter 576). Rarely, such patients have adrenal insufficiency as well.

Adrenal hypoplasia is also occasionally seen in patients with Pallister-Hall syndrome caused by mutations in the \( \text{GLIS3} \) oncogene (see Chapter 575).

Adrenoleukodystrophy

In adrenoleukodystrophy (ALD), adrenal cortical deficiency is associated with demyelination in the central nervous system (see Chapters 86.2 and 599.3). High levels of very-long-chain fatty acids are found in tissues and body fluids, resulting from their impaired \( \beta \)-oxidation in the peroxisomes.

The most common form of ALD is an \( X \)-linked disorder with various presentations. The most common clinical picture is of a degenerative neurologic disorder appearing in childhood or adolescence and progressing to severe dementia and deterioration of vision, hearing, speech, and gait, with death occurring within a few years. Neurologic symptoms may be subtle at onset, sometimes consisting only of behavioral changes or deteriorating academic performance. Generalized but incomplete alopecia, resembling that of chemotherapy, is a characteristic but inconsistent finding. A milder form of X-linked ALD is adrenomyeloneuropathy, which begins in later adolescence or early adulthood. Patients may have evidence of adrenal insufficiency before, at the time of, or after neurologic symptoms develop, often with years separating their presentation. X-linked ALD is caused by mutations in the \( \text{ABC1D1} \) gene located on Xq28. The gene encodes a transmembrane transporter involved in the importation of very-long-chain fatty acids into peroxisomes. More than 400 mutations have been described in patients with X-linked ALD. Clinical phenotypes can vary even within families, perhaps owing to modifier genes or other unknown factors. There is no correlation between the degree of neurologic impairment and severity of adrenal insufficiency. Prenatal diagnosis by DNA analysis and family screening by very-long-chain fatty acid assays and mutation analysis are available. Women who are heterozygous carriers of the X-linked ALD gene can develop symptoms in midlife or later; adrenal insufficiency is rare.

Neonatal ALD is a rare autosomal recessive disorder. Infants have neurologic deterioration and have or acquire evidence of adrenocortical dysfunction. Most patients have severe, progressive cognitive impairment and die before 5 yr of age. This disorder is a subset of Zellweger (cerebrohepatorenal) syndrome, in which peroxisomes do not develop at all owing to mutations in any of several genes (\( \text{PEX5} \), \( \text{PEX1} \), \( \text{PEX10} \), \( \text{PEX13} \), and \( \text{PEX26} \)) controlling the development of this organelle.

Familial Glucocorticoid Deficiency

Familial glucocorticoid deficiency is a form of chronic adrenal insufficiency characterized by isolated deficiency of glucocorticoids, elevated levels of ACTH, and generally normal aldosterone production, although salt-losing manifestations as are present in most other forms of adrenal insufficiency occasionally occur. Patients mainly have hypoglycemia, seizures, and increased pigmentation during the 1st decade of life. The disorder affects both sexes equally and is inherited in an autosomal recessive manner. There is marked adrenocortical atrophy with relative sparing of the zona glomerulosa. Mutations in the gene for the ACTH receptor (\( \text{MCR2} \)) have been described in approximately 25% of these patients, most of which affect trafficking of receptor molecules from the endoplasmic reticulum to the cell surface. Another 20% of cases are caused by mutations in \( \text{MRAP} \), which encodes a melanocyte receptor accessory protein required for this trafficking. Recently, mutations at new genetic loci have been identified, including...
the minichromosome maintenance-deficient 4 homolog (MCM4) and nicotinamide nucleotide transhydrogenase (NNT). These genes are involved in DNA replication and antioxidant defense, respectively. Patients with MCM4 mutations also have growth failure, increased chromosomal breakage, and natural killer cell deficiency.

Another syndrome of ACTH resistance occurs in association with achalasia of the gastric cardia and alacrima (triple A or Allgrove syndrome). These patients often have a progressive neurologic disorder that includes autonomic dysfunction, intellectual disability, motor neuropathy, and occasional deafness. This syndrome is also inherited in an autosomal recessive fashion, and the A4A4 gene has been mapped to chromosome 1q213. The encoded protein, aladin, might help regulate nucleocytoplasmic transport of other proteins.

Type I Autoimmune Polyendocrinopathy

Although autoimmune Addison disease most often occurs sporadically (see “Autoimmune Addison Disease” in Chapter 575.1), it can occur as a component of 2 syndromes, each consisting of a constellation of autoimmune disorders (see Chapter 566). **Type I autoimmune polyendocrinopathy** (APS-1), also known as autoimmune polyendocrinopathy–candidiasis–ectodermal dysplasia (APECED) syndrome, is inherited in a mendelian autosomal recessive manner, whereas APS-2 (see “Autoimmune Addison Disease” in Chapter 575.1) has complex inheritance. **Chronic mucocutaneous candidiasis** is most often the first manifestation of APS-1, followed by hypoparathyroidism and then by Addison disease, which typically develops in early adolescence. Other closely associated autoimmune disorders include gonadal failure, alopecia, vitiligo, keratopathy, enameled hypoplasia, nail dystrophy, intestinal malabsorption, and chronic active hepatitis. Hypothyroidism and type 1 diabetes mellitus occur in less than 10% of affected patients. Some components of the syndrome continue to develop as late as the 5th decade. Patients with APS-1 may have antibodies to the adrenal cytochrome P450 enzymes CYP21, CYP17, and CYP11A1. The presence of such antibodies indicates a high likelihood of the development of Addison disease or, in female patients, ovarian failure. Adrenal failure can evolve rapidly in APS-1; death in patients with a previous diagnosis and unexplained deaths in siblings of patients with APS-1 have been reported, indicating the need to closely monitor patients with APS-1 and to thoroughly evaluate apparently unaffected siblings of patients with this disorder.

The gene affected in APS-1 is designated autoimmune regulator-1 (AIRE1); it has been mapped to chromosome 21q22.3. The AIRE1 gene encodes a transcription factor that controls the expression of many proteins within the thymus, thus playing a critical role in the generation of immune tolerance. Many different mutations in the AIRE1 gene have been described in patients with APS-1, with 2 mutations (R257X and a 3-bp deletion) being most common. There has been autosomal dominant transmission in 1 kindred owing to a specific missense mutation (G228W).

Disorders of Cholesterol Synthesis and Metabolism

Patients with disorders of cholesterol synthesis or metabolism, including abetalipoproteinemia with deficient lipoprotein B-containing lipoproteins, and familial hypercholesterolemia, with decreased or impaired low-density lipoprotein receptors, have limited adrenocortical function. Adrenal insufficiency has been reported in patients with Smith-Lemli-Opitz syndrome, an autosomal recessive disorder manifesting with facial anomalies, microcephaly, limb anomalies, and developmental delay (see Chapter 86.3). Mutations in the gene coding for sterol Δ7-hydroxylase, mapped to 11q12-q13, resulting in impairment of the final step in cholesterol synthesis with marked elevation of 7-dehydrocholesterol, abnormally low cholesterol, and adrenal insufficiency, have been identified in Smith-Lemli-Opitz syndrome. Wolman disease is a rare autosomal recessive disorder caused by mutations in the gene encoding human lysosomal acid lipase on chromosome 10q23.2-23.3. Cholesteryl esters accumulate in lysosomes in most organ systems, leading to organ failure. Infants during the 1st or 2nd mo of life have hepatosplenomegaly, steatorrhea, abdominal distention, and failure to thrive. Adrenal insufficiency and bilateral adrenal calcification are present, and death usually occurs in the 1st yr of life.

Corticosteroid-Binding Globulin Deficiency and Decreased Cortisol-Binding Affinity

Corticosteroid-binding globulin deficiency and decreased cortisol-binding affinity result in low levels of plasma cortisol but normal urinary free cortisol and normal plasma ACTH levels. A high prevalence of hypotension and fatigue has been reported in some adults with abnormalities of corticosteroid-binding globulin deficiency.

ACQUIRED ETIOLOGIES

Autoimmune Addison Disease

The most common cause of Addison disease is autoimmune destruction of the glands. The glands may be so small that they are not visible at autopsy, and only remnants of tissue are found in microscopic sections. Usually, the medulla is not destroyed, and there is marked lymphocytic infiltration in the area of the former cortex. In advanced disease, all adrenocortical function is lost, but early in the clinical course, isolated cortisol deficiency can occur. Most patients have adrenal cytoplasmic antibodies in their plasma; 21-hydroxylase (CYP21) is the most commonly occurring biochemically defined autoantigen.

Addison disease can occur as a component of 2 autoimmune polyendocrinopathy syndromes. Type I (APS-1) was discussed previously. **Type II autoimmune polyendocrinopathy** (APS-2) consists of Addison disease associated with autoimmune thyroid disease (Schmidt syndrome) or type 1 diabetes (Carpenter syndrome). Gonadal failure, vitiligo, alopecia, and chronic atrophic gastritis, with or without pernicious anemia, can occur. Frequencies of the human leukocyte antigen (HLA)-D3 and HLA-D4 alleles are increased in these patients and appear to confer an increased risk for development of this disease; particular alleles at the major histocompatibility complex class I chain-related genes A and B (MICA and MICB) also are associated with this disorder. Polymorphisms in genes involved in other autoimmune disorders have been inconsistently associated with primary adrenal insufficiency, and their contribution to its pathogenesis must be regarded as uncertain. These include the class II, major histocompatibility complex, transactivator (CIITA), C-type lectin domain family 16, member A (CLEC16A), and protein tyrosine phosphatase, nonreceptor type 22 (PTPN22). The disorder is most common in middle-aged women and can occur in many generations of the same family. Antiadrenal antibodies, specifically antibodies to the CYP21, CYP17, and CYP11A1 enzymes, are also found in these patients. Autoimmune adrenal insufficiency may also be seen in patients with celiac disease (see Chapter 338.2).

Infection

Tuberculosis was a common cause of adrenal destruction in the past but is much less prevalent now. The most common infectious etiology for adrenal insufficiency is meningococcemia (see Chapter 191); adrenal crisis from this cause is referred to as the Waterhouse-Friderichsen syndrome. Patients with AIDS can have a variety of subclinical abnormalities in the hypothalamic-pituitary-adrenal axis, but frank adrenal insufficiency is rare. However, drugs used in the treatment of AIDS can affect adrenal hormone homeostasis.

Drugs

Ketoconazole, an antifungal drug, can cause adrenal insufficiency by inhibiting adrenal enzymes. Mitotane (o,p′-DDD), used in the treatment of adrenocortical carcinoma and refractory Cushting syndrome (see Chapters 577 and 579), is cytotoxic to the adrenal cortex and can also alter extradienoial cortisol metabolism. Signs of adrenal insufficiency occur in a substantial percentage of patients treated with mitotane. Etomidate, used in the induction and maintenance of general anesthesia, inhibits 11β-hydroxylase (CYP11B1), and a single induction dose can block cortisol synthesis for 4-8 hr or longer. This may be problematic in severely stressed patients, particularly if repeated doses
are used in a critical care setting. Although not themselves a cause of adrenal insufficiency, rifampicin and anticonvulsive drugs such as phenytoin and phenobarbital reduce the effectiveness and bioavailability of corticosteroid replacement therapy by inducing steroid metabolizing enzymes in the liver.

**Hemorrhage into Adrenal Glands**

Hemorrhage into adrenal glands can occur in the neonatal period as a consequence of a difficult labor (especially breech presentation), or its etiology might not be apparent (Fig. 575-1). An incidence rate of 3 in 100,000 live births has been suggested. The hemorrhage may be sufficiently extensive to result in death from exsanguination or hypoadrenalism. An abdominal mass, anemia, unexplained jaundice, or scrotal hematoma may be the presenting sign. Often, the hemorrhage is asymptomatic initially and is identified later by calcification of the adrenal gland. Fetal adrenal hemorrhage has also been reported. Postnatally, adrenal hemorrhage most often occurs in patients being treated with anticoagulants. It can also occur as a result of child abuse.

**Clinical Manifestations**

Primary adrenal insufficiency leads to cortisol and often aldosterone deficiency. The signs and symptoms of adrenal insufficiency are most easily understood in the context of the normal actions of these hormones (see Chapter 574; Table 575-4).

Hypoglycemia is a prominent feature of adrenal insufficiency. It is often accompanied by ketosis as the body attempts to use fatty acids as an alternative energy source. Ketosis is aggravated by anorexia, nausea, and vomiting, all of which occur frequently.

Cortisol deficiency decreases cardiac output and vascular tone; moreover, catecholamines such as epinephrine have decreased inotropic and pressor effects in the absence of cortisol. These problems are initially manifested as orthostatic hypotension in older children and can progress to frank shock in patients of any age. They are exacerbated by aldosterone deficiency, which results in hypovolemia owing to decreased resorption of sodium in the distal nephron.

Hypotension and decreased cardiac output decrease glomerular filtration and thus decrease the ability of the kidney to excrete free water. Vasopressin (AVP) is secreted by the posterior pituitary in response to hypotension and also as a direct consequence of lack of inhibition by cortisol. These factors decrease plasma osmolality and lead in particular to hyponatremia. Hyponatremia is also caused by aldosterone deficiency and may be much worse when both cortisol and aldosterone are deficient.

In addition to hypovolemia and hyponatremia, aldosterone deficiency causes hyperkalemia by decreasing potassium excretion.

*Prevalence data are for primary insufficiency only. Blanks indicate that no pediatric prevalence data are available.

in the distal nephron. Cortisol deficiency alone does not cause hyperkalemia.

Cortisol deficiency decreases negative feedback on the hypothalamic-pituitary axis, leading to increased secretion of ACTH. Hyperpigmentation is caused by ACTH and other peptide hormones (γ-melanocyte–stimulating hormone) arising from the ACTH precursor proopiomelanocortin. In patients with a fair complexion, the skin can have a bronze cast. Pigmentation may be more prominent in skin creases, mucosa, and scars. In dark-skinned patients, it may be most readily appreciated in the gingival and buccal mucosa.

The clinical presentation of adrenal insufficiency depends on the age of the patient, whether both cortisol and aldosterone secretion are affected, and to some extent on the underlying etiology. The most common causes in early infancy are inborn errors of steroid biosynthesis, sepsis, AHC, and adrenal hemorrhage. Infants have a relatively greater requirement for aldosterone than do older children, possibly owing to immaturity of the kidney and also to the low sodium content of human breast milk and infant formula. Hyperkalemia, hyponatremia, and hypoglycemia are prominent presenting signs of adrenal insufficiency in infants. Ketosis is not consistently present because infants generate ketones less well than do older children. Hyperpigmentation is not usually seen because this takes weeks or months to develop, and orthostatic hypotension is obviously difficult to demonstrate in infants.

Infants can become ill very quickly. There may be only a few days of decreased activity, anorexia, and vomiting before critical electrolyte abnormalities develop.

In older children with Addison disease, symptoms include muscle weakness, malaise, anorexia, vomiting, weight loss, and orthostatic hypotension. These may be of insidious onset. It is not unusual to elicit, in retrospect, an episodic history spanning years with symptoms being noticeable only during intercurrent illnesses. Such patients can present with acute decompensation (adrenal crisis) during relatively minor infectious illnesses. Some of these patients have been initially misdiagnosed with chronic fatigue syndrome, postmononucleosis syndrome, chronic Lyme disease, or psychiatric disorders (depression or anorexia nervosa).

Hyperpigmentation is often, but not necessarily, present. Hyponatremia is present at diagnosis in almost 90% of patients. Hyperkalemia tends to occur later in the course of the disease in older children than in infants and is present in only half of patients at diagnosis. Normal potassium levels must never be presumed to rule out primary adrenal insufficiency.

Hypoglycemia and ketosis are common. Thus, the clinical presentation can be easily confused with gastroenteritis or other acute infections. Chronicity of symptoms can alert the clinician to the possibility of Addison disease, but this diagnosis should be considered in any child with orthostatic hypotension, hyponatremia, hypoglycemia, and ketosis. Salt craving is seen in primary adrenal insufficiency with mineralocorticoid deficiency. Fatigue, myalgias, fever, eosinophilia, lymphocytosis, hypercalcemia, and anemia may be noted with glucocorticoid deficiency.

**LABORATORY FINDINGS**

Hypoglycemia, ketosis, hyponatremia, and hyperkalemia have been discussed. An electrocardiogram is useful for quickly detecting hyperkalemia in a critically ill child. Acidosis is often present, and the blood urea nitrogen level is elevated if the patient is dehydrated.

Cortisol levels are sometimes at the low end of the normal range but are invariably low when the patient’s degree of illness is considered. ACTH levels are high in primary adrenal insufficiency but can take time to be reported by the laboratory. Similarly, aldosterone levels may be within the normal range but inappropriately low considering the patient’s hyponatremia, hyperkalemia, and hypovolemia. Plasma renin activity is elevated. Blood eosinophils may be increased in number, but this is rarely useful diagnostically.

Urinary excretion of sodium and chloride are increased and urinary potassium is decreased, but these are difficult to assess on random urine samples. Accurate interpretation of urinary electrolytes requires more-prolonged (24 hr) urine collections and knowledge of the patient’s sodium and potassium intake.

The most definitive test for adrenal insufficiency is measurement of serum levels of cortisol before and after administration of ACTH; resting levels are low and do not increase normally after administration of ACTH. Occasionally, normal resting levels that do not increase after administration of ACTH indicate an absence of adrenocortical reserve. A low initial level followed by a significant response to ACTH can indicate secondary adrenal insufficiency. Traditionally, this test has been performed by measuring cortisol levels before and 30 or 60 min after giving 0.250 mg of cosyntropin (ACTH 1-24) by rapid intravenous infusion. Aldosterone will transiently increase in response to this dose of ACTH and may also be measured. A low-dose test (1 µg ACTH 1-24/1.73 m²) is a more sensitive test of pituitary-adrenal reserve, but it has somewhat lower specificity (more false-positive tests).

**DIFFERENTIAL DIAGNOSIS**

Upon presentation, Addison disease often needs to be distinguished from more acute illnesses such as gastroenteritis with dehydration or sepsis. Additional testing is directed at identifying the specific cause for adrenal insufficiency. When congenital adrenal hyperplasia is suspected, serum levels of cortisol precursors (17-hydroxyprogesterone) should be measured along with cortisol in an ACTH stimulation test (see Chapter 576). Elevated levels of very-long-chain fatty acids are diagnostic of ALD (see Chapter 599.3). Many genetic etiologies for primary adrenal insufficiency may be identified by direct genetic testing, but it can take many weeks for results to become available. The presence of antidiuretic antibodies suggests an autoimmune pathogenesis. Patients with autoimmune Addison disease must be closely observed for the development of other autoimmune disorders. In children, hypoparathyroidism is the most commonly associated disorder, and it is suspected if hypocalcemia and elevated phosphate levels are present.

Ultrasonography (which requires an experienced operator), CT, or MRI can help define the size of the adrenal glands.

**TREATMENT**

Treatment of acute adrenal insufficiency must be immediate and vigorous. If the diagnosis of adrenal insufficiency has not been established, a blood sample should be obtained before therapy to determine electrolytes, glucose, ACTH, cortisol, aldosterone, and plasma renin activity. If the patient’s condition permits, an ACTH stimulation test can be performed while initial fluid resuscitation is underway. An intravenous solution of 5% glucose in 0.9% saline should be administered to correct hypoglycemia, hypovolemia, and hyponatremia. Hypotonic fluids (e.g., 5% glucose in water or 0.2% saline) must be avoided because they can precipitate or exacerbate hyperkalemia. If hyperkalemia is severe, it can require treatment with intravenous calcium and/or bicarbonate, intrarectal potassium-binding resin (Kayexalate), or intravenous infusion of glucose and insulin. A watersoluble form of hydrocortisone, such as hydrocortisone sodium succinate, should be given intravenously. As much as 10 mg for infants, 25 mg for toddlers, 50 mg for older children, and 100 mg for adolescents should be administered as a bolus and a similar total amount given in divided doses at 6 hr intervals for the first 24 hr. These doses may be reduced during the next 24 hr if progress is satisfactory. Adequate fluid and sodium repletion is achieved by intravenous saline administration, aided by the mineralocorticoid effect of high doses of hydrocortisone.

Particular caution should be exercised in the rare patient with concomitant adrenal insufficiency and thyrotoxicosis, because thyroxine can increase cortisol clearance. Thus, an adrenal crisis may be precipitated if thyrotoxicosis is treated without first ensuring adequate glucocorticoid replacement.

After the acute manifestations are under control, most patients require chronic replacement therapy for their cortisol and aldosterone deficiencies. Hydrocortisone (cortisol) may be given orally in daily doses of 10 mg/m²/24 hr in 3 divided doses; some patients require 15 mg/m²/24 hr to minimize fatigue, especially in the morning.
Timed-release preparations of hydrocortisone are undergoing clinical trials but are not yet generally available. Equivalent doses (20-25% of the hydrocortisone dose) of prednisone or prednisolone may be divided and given twice daily. ACTH levels may be used to monitor adequacy of glucocorticoid replacement in primary adrenal insufficiency; in congenital adrenal hyperplasia, levels of precursor hormones are used instead (see Chapter 576). Blood samples for monitoring should be obtained at a consistent time of day and in a consistent relation to (i.e., before or after) the hydrocortisone dose. Normalizing ACTH levels is unnecessary when mineralocorticoid dosages are increased. Aldosterone secretion is unaffected in secondary adrenal insufficiency.

If aldosterone deficiency is present, fludrocortisone, a synthetic mineralocorticoid, is given orally in doses of 0.05-0.2 mg daily. Measurements of plasma renin activity are useful in monitoring the adequacy of mineralocorticoid replacement. Chronic overdosage with glucocorticoids leads to obesity, short stature, and osteoporosis, whereas overdosage with fludrocortisone results in hypertension and occasionally hypokalemia.

Replacement of dehydroepiandrosterone (DHEA) in adults remains controversial; prepubertal children do not normally secrete large amounts of DHEA. Many adults with Addison disease complain of having decreased energy, and replacing DHEA can improve this problem, particularly in women in whom adrenal androgens represent approximately 50% of total androgen secretion.

Additional therapy might need to be directed at the underlying cause of the adrenal insufficiency in regard to infections and certain metabolic defects. Therapeutic approaches to AILD include administration of glycerol trioleate and glycerol trirucate (Lorenzo’s oil), bone marrow transplantation, and lovastatin (see Chapter 599). Some children with pituitary abnormalities have hypoplasia of the septum pellucidum. The latter type of abnormality is termed septooptic dysplasia, or de Morsier syndrome (see Chapter 591). More-severe developmental anomalies of the brain, such as anencephaly and holoprosencephaly, can also affect the pituitary. These disorders are usually sporadic, although a few cases of autosomal recessive inheritance have occurred. Isolated deficiency of corticotropin has been reported, including in several sets of siblings. Patients with multiple pituitary hormone deficiencies caused by mutations in the PRO1 gene have been described with progressive ACTH/cortisol deficiency. Isolated deficiency of corticotropin-releasing hormone has been documented in an Arab kindred as an autosomal recessive trait.

It was recently recognized that up to 60% of children with Prader-Willi syndrome (see Chapter 81.8) have some degree of secondary adrenal insufficiency as assessed by provocative testing with metyrapone (see “Laboratory Findings” in Chapter 575.2), although diurnal cortisol levels are normal. The clinical significance of this finding is uncertain, but it might contribute to the relatively high incidence of sudden death with infectious illness that occurs in this population. Although it is not yet a standard of care, some endocrinologists advocate treating patients who have Prader-Willi syndrome with hydrocortisone during febrile illness.

**Corticotropin (Adrenocorticotropic Hormone) Deficiency**

Pituitary or hypothalamic dysfunction can cause corticotropin deficiency (see Chapter 557), usually associated with deficiencies of other pituitary hormones such as growth hormone and thyrotropin. Destructive lesions in the area of the pituitary, such as craniopharyngioma and germinoma, are the most common causes of corticotropin deficiency. In many cases, the pituitary or hypothalamus is further damaged during surgical removal or radiotherapy of tumors in the midline of the brain. Traumatic brain injury (see Chapter 710) frequently causes pituitary dysfunction, especially in the first days after the injury. However, corticotropin deficiency is difficult to detect then owing to frequent use of high doses of dexamethasone to minimize brain swelling, and permanent corticotropin deficiency is unusual after traumatic brain injury. In rare instances, autoimmune hypophysitis is the cause of corticotropin deficiency.

Congenital lesions of the pituitary also occur. The pituitary alone may be affected, or additional midline structures may be involved, such as the optic nerves or septum pellucidum. The latter type of abnormality is termed septooptic dysplasia, or de Morsier syndrome (see Chapter 591.9). More-severe developmental anomalies of the brain, such as anencephaly and holoprosencephaly, can also affect the pituitary. These disorders are usually sporadic, although a few cases of autosomal recessive inheritance have occurred. Isolated deficiency of corticotropin has been reported, including in several sets of siblings. Patients with multiple pituitary hormone deficiencies caused by mutations in the PRO1 gene have been described with progressive ACTH/cortisol deficiency. Isolated deficiency of corticotropin-releasing hormone has been documented in an Arab kindred as an autosomal recessive trait.

When secondary adrenal insufficiency is the consequence of an inborn or acquired anatomic defect involving the pituitary, there may be signs of associated deficiencies of other pituitary hormones. The penis may be small in male infants if gonadotropins are also deficient. Infants with secondary hypothroidism are often jaundiced. Children with associated growth hormone deficiency grow poorly after the 1st yr of life.

Some children with pituitary abnormalities have hypoplasia of the midface. Children with optic nerve hypoplasia can have obvious visual impairment. They usually have a characteristic wandering nystagmus, but this is often not apparent until several months of age.

**Laboratory Findings**

Because the adrenal glands themselves are not directly affected, the diagnosis of secondary adrenal insufficiency is sometimes challenging. Historical gold standard dynamic tests include insulin-induced hypoglycemia, which provides a potent stress to the entire hypothalamic-pituitary-adrenal (HPA) axis. This test requires constant attendance by a physician and is considered by many endocrinologists to be too dangerous for routine use. A second gold standard test uses metyrapone, a specific inhibitor of steroid 11β-hydroxylase (CYP11B1) to
Bibliography
Adrenal Insufficiency in the Critical Care Setting

**Etiology**

Adrenal insufficiency in the context of critical illness is encountered in up to 20-50% of pediatric patients, often as a transient condition. In many cases, it is considered to be "functional" or "relative" in nature, meaning that cortisol levels are within normal limits but cannot increase sufficiently to meet the demands of critical illness. The causes are heterogeneous, and some were discussed in Chapter 575.1. They include adrenal hypoperfusion from shock, particularly septic shock, as is often seen in meningococcemia. Inflammatory mediators during septic shock, particularly interleukin-6, can suppress ACTH secretion, directly suppress cortisol secretion, or both. Tumors, usually as adenomas or carcinomas, can secrete ACTH and thus block cortisol synthesis, thus removing the normal negative feedback of cortisol on ACTH secretion. There are several protocols for this test; one version administers 30 mg/kg of metyrapone orally at midnight, with a blood sample obtained for cortisol and 11-deoxycortisol (the substrate for 11β-hydroxylase) at 8 AM. A low cortisol level (<5 µg/dL) demonstrates adequate suppression of cortisol synthesis, and an 11-deoxycortisol level >7 µg/dL indicates that ACTH has responded normally to the cortisol deficiency by stimulating the adrenal cortex. This test should be used with caution outside the research setting because it can precipitate adrenal crises in patients with marginal adrenal function; the drug is not available in all locales.

At present, the most commonly used test to diagnose secondary adrenal insufficiency is low-dose ACTH stimulation testing (1 µg/1.73 m² of cosyntropin given intravenously), the rationale being that there will be some degree of atrophy of the adrenal cortex if normal physiologic ACTH stimulation is lacking. Thus, this test may be falsely negative in cases of acute compromise of the pituitary (e.g., injury or surgery). Such circumstances rarely pose a diagnostic dilemma; in general, this test provides excellent sensitivity and specificity. Although assays vary somewhat, a threshold cortisol level of 18-20 µg/dL 30 min after cosyntropin administration may be used to dichotomize normal and abnormal responses.

At present, there seems to be little reason to use stimulation with corticotropin-releasing hormone instead of ACTH; although the corticotropin-releasing hormone test has the theoretical advantage of testing the ability of the anterior pituitary to respond to this stimulus by secreting ACTH (thus distinguishing secondary and tertiary adrenal insufficiency), in practice it does not provide improved sensitivity and specificity, and the agent is not as widely available.

**Treatment**

Iatrogenic secondary adrenal insufficiency (caused by chronic glucocorticoid administration) is best avoided by use of the smallest effective doses of systemic glucocorticoids for the shortest period of time. When a patient is thought to be at risk, tapering the dose rapidly to a level equivalent to or slightly less than the physiologic replacement level (approximately 10 mg/m²/24 hr of hydrocortisone) and further tapering over several weeks can allow the adrenal cortex to recover without development of signs of adrenal insufficiency. Patients with anatomic lesions of the pituitary should be treated indefinitely with glucocorticoids. Mineralocorticoid replacement is not required. In patients with panhypopituitarism, treating cortisol deficiency can increase free water excretion, thus unmasking central diabetes insipidus. Electrolytes must be monitored carefully when initiating cortisol therapy in panhypopituitarism patients.

575.4 Altered End-Organ Sensitivity to Corticosteroids

**Etiology**

Patients with generalized glucocorticoid resistance have target-tissue insensitivity to glucocorticoids. The condition is usually inherited in an autosomal dominant manner but sporadic cases occur. Impairment of normal negative feedback of cortisol at the levels of the hypothalamus and pituitary activates the HPA axis with consequent increases in ACTH and cortisol concentrations. Generalized glucocorticoid resistance is caused by mutations in the glucocorticoid receptor (encoded by the gene) that have been previously treated with systemic corticosteroids (e.g., children with leukemia) and have suppression of the HPA axis for that reason. In the intensive care nursery, premature infants have not yet developed normal cortisol biosynthetic capacity (see Chapter 574.2) and thus may not be able to secrete adequate amounts of this hormone when ill.
Bibliography
Bibliography

by the NR3C1 gene) that impair its action by interfering with ligand binding, DNA binding, transcriptional activation, or some combination of these. Most mutations are heterozygous; glucocorticoid receptors usually bind DNA as dimers, and 3 out of every 4 dimers will contain at least 1 abnormal receptor molecule when a heterozygous mutation is present.

**Clinical Manifestations**

The excess ACTH secretion causes adrenal hyperplasia with increased production of adrenal steroids with mineralocorticoid activity, including cortisol, deoxycorticosterone, and corticosterone, and also androgens and precursors, including androstenedione, dehydroepiandrosterone, and dehydroepiandrosterone sulfate. The high cortisol concentrations do not cause Cushing syndrome (see Chapter 577) because of the insensitivity to glucocorticoids; conversely, most signs and symptoms of adrenal insufficiency are absent except for the frequent occurrence of chronic fatigue and occasional anxiety (neonatal hypoglycemia was reported in 1 very unusual patient with a homozygous null mutation). On the other hand, the mineralocorticoid and androgen receptors are normally sensitive to their ligands. Signs of mineralocorticoid excess, such as hypertension and hypokalemic alkalosis, are frequently noted. The increased concentrations of adrenal androgens may cause ambiguous genitalia in girls and gonadotropin-independent precocious puberty in children of either gender; acne; hirsutism, and infertility in both sexes; menstrual irregularities in females; and oligospermin in males. Testicular adrenal rest tumors and ACTH-secreting pituitary adenomas occasionally occur.

**Laboratory Findings**

The diagnosis of generalized glucocorticoid resistance is suggested by elevated serum cortisol concentrations and increased 24 hr urinary free cortisol excretion in the absence of Cushing syndrome. Levels of other adrenal steroids are also increased. Plasma concentrations of ACTH may be normal or high. The circadian pattern of ACTH and cortisol secretion is preserved, although at higher-than-normal concentrations, and there is resistance of the HPA axis to dexamethasone suppression. Sequencing of the NR3C1 gene can confirm the diagnosis, but is not routinely available.

**Differential Diagnosis**

Generalized glucocorticoid resistance should be distinguished from relatively mild cases of Cushing syndrome (whether caused by a pituitary adenoma or adrenal tumor, see Chapter 577); the latter is more likely to be associated with excessive weight gain or poor linear growth. Adrenocortical tumors may secrete mineralocorticoids such as deoxycorticosterone and also androgens, but ACTH levels are often suppressed and of course the tumor can usually be visualized with appropriate imaging techniques. Congenital adrenal hyperplasia (see Chapter 576), particularly 11β-hydroxylase deficiency, may present with hypertension and signs of androgen excess, but in that condition cortisol levels are low and levels of cortisol precursors (17-hydroxyprogesterone, 11-deoxycortisol) are elevated. Obese patients may be hypertensive and have hyperandrogenism, but cortisol secretion should be readily suppressed by dexamethasone.

**Treatment**

The goal of treatment is to suppress the excess secretion of ACTH, thereby suppressing the increased production of adrenal steroids with mineralocorticoid and androgenic activity. This requires administration of high doses of a pure glucocorticoid agonist such as dexamethasone (typically ~20–40 μg/kg/day) with careful titration to suppress endogenous corticosteroid secretion without causing signs of glucocorticoid excess such as excessive weight gain or suppression of linear growth.

**CORTISONE REDUCTASE DEFICIENCY**

**Etiology**

Levels of active glucocorticoids in target tissues are modulated by 2 isozymes of 11β-hydroxysteroid dehydrogenase. The 11-HSD2 isozyme converts cortisol to an inactive metabolite, cortisone; the 2 steroids differ in the presence of an 11β-hydroxyl vs an 11-oxo group, respectively. Mutations in this enzyme cause the syndrome of apparent mineralocorticoid excess. Conversely, the 11-HSD1 isozyme converts cortisone to cortisol, and so it is sometimes referred to as “cortisone reductase.” This isozyme is expressed at high levels in glucocorticoid target tissues, particularly the liver, where it ensures adequate levels of active glucocorticoids (cortisol and corticosterone) to meet metabolic demands without requiring excessive adrenal cortisol secretion.

The 11-HSD1 isozyme is located in the endoplasmic reticulum (i.e., it is a “microsomal” enzyme) and functions as a dimer. It accepts electrons from reduced nicotine–adenine dinucleotide phosphate, which is generated within the endoplasmic reticulum by hexose-6-phosphate dehydrogenase, an enzyme distinct from cytoplasmic glucose-6-phosphate dehydrogenase.

Apparent cortisone reductase deficiency is caused by homozygous mutations in hexose-6-phosphate dehydrogenase that prevent generation of reduced nicotine–adenine dinucleotide phosphate within the endoplasmic reticulum and thus starve 11-HSD1 of its essential cofactor for the reductase reaction. Very rare patients have been reported to have heterozygous mutations in the HSD11B1 gene encoding 11-HSD1 itself and thus have “true” cortisone reductase deficiency; because the enzyme functions as a homodimer, heterozygous mutations are able to impair three fourths of all dimmers.

**Clinical Manifestations**

Because circulating cortisone is not converted to cortisol, the circulating half-life of cortisol is decreased and the adrenal cortex must secrete additional cortisol to compensate. This leads to adrenocortical overactivity analogous to, but generally much milder than, that seen in generalized glucocorticoid resistance. This is usually not severe enough to cause hypertension, presenting instead with mild to moderate signs of androgen excess such as hirsutism, oligomenorrhea or amenorrhea, and infertility in females, and precocious pseudopuberty (axillary and pubic hair, and penile enlargement, but not testicular enlargement) in males.

**Laboratory Findings**

The ratio of cortisol to cortisone in blood is lower than usual. The same is true of urinary metabolites, typically measured as a ratio of the sum of the tetrahydrocortisol and allo tetrahydrocortisol excretion to that of tetrahydrocortisone. These determinations are best accomplished by gas chromatography followed by mass spectrometry, and are available in specialized reference laboratories. Absolute levels of cortisol and ACTH are within normal limits.

**Differential Diagnosis**

Cortisone reductase deficiency has to be distinguished from, and is much less common than, other causes of androgen excess such as polycystic ovarian syndrome and nonclassical congenital adrenal hyperplasia as a result of 21-hydroxylase deficiency.

**Treatment**

Treatment is aimed at decreasing adrenal overactivity and thus reducing secretion of androgens. This can be accomplished by administration of hydrocortisone.

**ALTERED END-ORGAN SENSITIVITY TO MINERALOCORTICOIDS**

**Pseudohypoaldosteronism**

**Etiology**

Pseudohypoaldosteronism type 1 (PHA1) is a monogenic disease in which aldosterone action is deficient and patients are thus unable to resorb urinary sodium or excrete potassium properly. There are 2 forms. A relatively mild autosomal dominant form is caused by mutations in the NR3C2 gene encoding the human mineralocorticoid receptor. As with generalized glucocorticoid resistance, a heterozygous mutation is sufficient to cause disease because the
mineralocorticoid receptor interacts with DNA as a dimer, and three fourths of the dimers are defective in individuals carrying heterozygous mutations (assuming mutant protein is synthesized). A more severe autosomal recessive form is usually the result of homozygous mutations in the α (SCNN1A), β (SCNN1B), or γ (SCNN1G) subunits of the epithelial Na(+) channel, but 1 reported case of severe autosomal recessive disease was caused by homozygous mutations in NR3C2.

PHA1 should not be confused with pseudohypoaldosteronism type 2, a rare mendelian syndrome characterized by hyperkalemia and, in contrast to PHA1, by hypertension from excessive renal salt reabsorption. This disorder is caused by mutations in the renal regulatory kinases, WNK1 and WNK4, or components of an E3 ubiquitin ligase complex Kelch-like 3 (KLHL3) and Cullin 3 (CUL3).

**Clinical Manifestations**
Infants with PHA1 present with hyperkalemia, hyponatremia, hypovolemia, hypotension, and failure to thrive. In more-severe (usually autosomal recessive) cases, salt loss is not confined to the kidney but instead occurs from most epithelia. Mothers may report that the skin of their affected infants tastes salty. Some infants suffer from cystic fibrosis-like pulmonary symptoms. It is often difficult to control electrolyte abnormalities in patients with the autosomal recessive form, leading to frequent hospitalizations and a need for close clinical monitoring.

It is noteworthy that signs and symptoms of aldosterone deficiency tend to remit as the patients get older, particularly in the autosomal dominant form. This is similar to what is seen in actual aldosterone deficiency as occurs in the salt-losing forms of congenital adrenal hyperplasia or aldosterone synthase deficiency. The kidney matures after early infancy to become more efficient at excreting potassium, and whereas breast milk and infant formula are low in sodium, the normal adult Western diet is relatively high in sodium, thus compensating for the renal salt wasting.

**Laboratory Findings**
Infants have marked hyperkalemia and hyponatremia. Both plasma renin and aldosterone are markedly elevated. Levels of cortisol and ACTH are normal. If hypovolemia is severe, patients may develop prerenal azotemia. The electrocardiogram may include tall peaked T waves with severe hyperkalemia or ventricular tachycardia.

**Differential Diagnosis**
PHA in infants should be distinguished from other causes of hyperkalemia and hyponatremia. These include renal failure of any cause, congenital adrenal hyperplasia, aldosterone synthase deficiency, and other causes of adrenocortical insufficiency such as AHC. Patients with renal failure will have elevated blood urea nitrogen and creatinine, but these may be seen in severely dehydrated patients with PHA. Patients with any form of adrenal insufficiency in this clinical context will have low or low-normal aldosterone levels (with elevated plasma renin), in contrast to the elevated aldosterone levels seen in PHA. Patients with congenital adrenal hyperplasia have elevated levels of steroid precursors such as 17-hydroxyprogesterone (in patients with 21-hydroxylase deficiency), and patients with most forms of adrenal insufficiency have elevated ACTH levels.

**Treatment**
Infants must be given dietary sodium supplementation (initially intravenous and then oral), typically approximately 8 mEq/kg/day. Potassium levels in the infant formula often need to be reduced, which may be accomplished by mixing the formula with polystyrene resin (Kayexalate) and then decanting the formula prior to feeding. Fludrocortisone, a synthetic mineralocorticoid, may be efficacious in milder autosomal dominant cases if administered in high doses (titrating up to ~0.5 mg daily). Significant electrolyte abnormalities require treatment with intravenous normal saline and rectal polystyrene resin. Severe hyperkalemia may require glucose and insulin infusions to control.

**APPARENT MINERALOCORTICOID EXCESS**

**Etiology**
The syndrome of apparent mineralocorticoid excess is an autosomal recessive disorder caused by mutations in the HSD11B2 gene encoding the 11-HSD2 isozyme of 11β-hydroxysteroid dehydrogenase. The mineralocorticoid receptor actually has nearly identical affinities for aldosterone (the main mineralocorticoid hormone) and cortisol, yet cortisol is normally only a weak mineralocorticoid in vivo. This is because 11-HSD2 is expressed along with the mineralocorticoid receptor in most target tissues such as the renal cortical collecting duct epithelium. It converts cortisol to cortisone, which is not an active steroid, thus preventing it from occupying the mineralocorticoid receptor. In contrast, aldosterone is not a substrate for the enzyme because its 11β-hydroxyl group forms a hemiketal with the 18-aldehyde group of the steroid and is thus not accessible to the enzyme. Thus, in the absence of 11-HSD2, cortisol is able to efficiently occupy the mineralocorticoid receptor, and because cortisol concentrations are normally far higher than those of aldosterone, this results in signs and symptoms of mineralocorticoid excess.

A similar clinical picture occurs with excessive consumption of licorice or licorice-flavored chewing tobacco; licorice contains compounds including glycyrrhetinic and glycyrrhizic acids that inhibit 11-HSD2. Carbenoxolone, an antihypertensive drug that is not marketed in the United States, has similar effects.

**Clinical Manifestations**
Affected infants often have some degree of intrauterine growth restriction with birth weights of 2 kg typical for term infants. Infants and children often fail to thrive. Severe hypertension (to ~200/120 mm Hg) is almost always present. In some patients, the hypertension tends to be labile or paroxysmal with severe emotional stress as a precipitating factor. Complications of hypertension have included cerebrovascular accidents. Several patients have died during infancy or adolescence, either from electrolyte imbalances leading to cardiac arrhythmias or from vascular sequelae of hypertension. Hypokalemic alkalosis can eventually cause nephrocalcinosis (often visible on renal ultrasounds) and nephrogenic diabetes insipidus leading to polyuria and polydipsia. Deleterious effects on muscle range from elevations in serum creatine phosphokinase to frank rhabdomyolysis. Electrocardiograms show left ventricular hypertrophy.

**Laboratory Findings**
Hypokalemia and alkalosis are common but not persistent. Sodium levels are generally in the upper part of the reference range. Aldosterone and renin levels are very low because the hypertension and hyperkalemia are independent of aldosterone concentrations. Serum cortisol and ACTH levels are generally within normal limits. The serum half-life of cortisol is increased, but the test for this requires a radioactive tracer and is not clinically available. Total urinary excretion of cortisol metabolites is markedly decreased. The urinary ratio of free cortisol to free cortisone is elevated, as is the ratio of urinary tetrahydrocortisol plus allotetrahydrocortisol to tetrahydrocortisone.

**Differential Diagnosis**
The differential diagnosis includes other forms of severe childhood hypertension such as renal artery anomalies, but relatively few conditions present with suppressed renin and aldosterone levels. Liddle syndrome has a similar presentation but no abnormalities in the steroid profile, typically has an autosomal dominant mode of inheritance, and does not respond to treatment with mineralocorticoid receptor antagonists. Hypertensive forms of congenital adrenal hyperplasia (see Chapter 576) also have suppressed renin and aldosterone levels, but they present with signs of androgen excess (11β-hydroxylase deficiency) or androgen deficiency (17α-hydroxylase deficiency); the latter can be difficult to appreciate in young children. The steroid profiles in congenital adrenal hyperplasia differ from those seen in apparent mineralocorticoid excess syndrome.

Patients with severe Cushing syndrome may have high enough cortisol levels to overwhelm renal 11-HSD2, leading to severe...
hypertension with alterations in urinary cortisol-to-cortisone ratios. This occurs most often in patients with the ectopic ACTH syndrome. This generally does not present a diagnostic dilemma, because of the other signs of Cushing syndrome including high cortisol levels.

Treatment
Treatment includes a low-salt diet, potassium supplementation, and mineralocorticoid receptor blockade with spironolactone or eplerenone; a sodium channel blocker, such as amiloride or triamterene may work at least as well. In principle, suppression of cortisol secretion with dexamethasone (which does not bind the mineralocorticoid receptor) should work, but in practice it is much less effective than mineralocorticoid receptor blockade.

LIDDLE SYNDROME
Etiology
Liddle syndrome is a form of hypertension and hypokalemia that is clinically similar to the syndrome of apparent mineralocorticoid excess, but it is inherited in an autosomal dominant manner. It is caused by activating mutations in the β (SCNN1B) or γ (SCNN1G) subunits of the epithelial sodium channel. Most of these mutations prevent the channel subunits from being ligated to ubiquitin and targeted to the proteosome for degradation, a process that is normally regulated indirectly by aldosterone. The net effect is to increase the number of open channels at the apical surface of epithelial cells of the renal collecting duct, thus facilitating sodium resorption and potassium excretion. This disorder is thus the exact opposite of the autosomal recessive form of pseudohypoaldosteronism discussed previously.

Clinical Manifestations, Laboratory Findings, and Differential Diagnosis
Liddle syndrome is characterized by severe early-onset hypertension and by hypokalemia, which may not be persistent. Aldosterone and renin levels are suppressed but all steroid hormone levels are normal.

The differential diagnosis is the same as that for apparent mineralocorticoid excess.

Treatment
The mainstays of treatment are a low-salt diet, potassium supplementation, and a sodium channel blocker such as amiloride or triamterene. Mineralocorticoid receptor antagonists such as spironolactone are ineffective.

**Altered End-Organ Sensitivity to Mineralocorticoids**

**Apparent Mineralocorticoid Excess**

**Liddle Syndrome**
Congenital adrenal hyperplasia (CAH) is a family of autosomal recessive disorders of cortisol biosynthesis (normal adrenal steroidogenesis is discussed in Chapter 574). Cortisol deficiency increases secretion of corticotropin (adrenocorticotropic hormone [ACTH]), which, in turn, leads to adrenocortical hyperplasia and overproduction of intermediate metabolites. Depending on the enzymatic step that is deficient, there may be signs, symptoms, and laboratory findings of mineralocorticoid deficiency or excess; incomplete virilization or precocious puberty in affected males; and virilization or sexual infantilism in affected females (Figs. 576-1 and 576-2 and Table 576-1).

576.1 Congenital Adrenal Hyperplasia Caused by 21-Hydroxylase Deficiency

**ETIOLOGY**

More than 90% of CAH cases are caused by 21-hydroxylase deficiency. This P450 enzyme (CYP21, P450c21) hydroxylates progesterone and 17-hydroxyprogesterone to yield 11-deoxycorticosterone and 11-deoxycortisol, respectively (see Fig. 574-1 in Chapter 574). These conversions are required for synthesis of aldosterone and cortisol, respectively. Both hormones are deficient in the most-severe, “salt-wasting” form of the disease. Slightly less-severely affected patients are able to synthesize adequate amounts of aldosterone but have elevated levels of androgens of adrenal origin; this is termed “simple virilizing disease”. These 2 forms are collectively termed classic 21-hydroxylase deficiency. Patients with nonclassic disease have relatively mildly elevated levels of androgens and may be asymptomatic or have signs of androgen excess at any time after birth. Clinical presentation is dependent, in part, on the genotype (see below, “Genetics”) (Table 576-2).

**EPIDEMIOLOGY**

Classic 21-hydroxylase deficiency occurs in approximately 1 in 15,000-20,000 births in most populations. Approximately 70% of affected infants have the salt-losing form, whereas 30% have the simple virilizing form of the disorder. In the United States, CAH is less common in African-Americans compared with white children (1:42,000 vs 1:15,500). Nonclassic disease has a prevalence of approximately 1 in 1,000 in the general population, but occurs more frequently in specific ethnic groups such as Ashkenazi Jews and Hispanics.

**GENETICS**

There are 2 steroid 21-hydroxylase genes—CYP21P (CYP21A1P, CYP21A) and CYP21 (CYP21A2, CYP21B)—which alternate in tandem with 2 genes for the fourth component of complement (C4A and C4B) in the human leukocyte antigen (HLA) major histocompatibility complex on chromosome 6p21.3 between the HLA-B and HLA-DR loci. Many other genes are located in this cluster. CYP21 is the active gene; CYP21P is 98% identical in DNA sequence to CYP21 but is a pseudogene because of 9 different mutations. More than 90% of mutations causing 21-hydroxylase deficiency are recombinations between CYP21 and CYP21P. Approximately 20% are deletions generated by unequal meiotic crossing-over between CYP21 and CYP21P. In these cases, the severity of disease expression is largely determined by the activity of the less-severely affected of the 2 alleles.

Closely adjacent to, but on the opposite DNA strand from, CYP21 is the tenascin-X (TNX) gene, which encodes a connective tissue protein. Rarely, deletions of CYP21 extend into TNX. Such patients may have a contiguous gene syndrome (see Chapter 81.1) consisting of CAH and Ehlers-Danlos syndrome (see Chapters 484 and 659).
Figure 576-1 A, A 6-yr-old girl with congenital virilizing adrenal hyperplasia. The height age was 8.5 yr, and the bone age was 13 yr. B, Notice the clitoral enlargement and labial fusion. C, Her 5 yr old brother was not considered to be abnormal by the parents. The height age was 8 yr, and the bone age was 12.5 yr.

Figure 576-2 Three virilized females with untreated congenital adrenal hyperplasia. All were erroneously assigned male sex at birth, and each had a normal female sex-chromosome complement. Infants A and B had the salt-wasting form and received the diagnosis early in infancy. Infant C was referred at 1 yr of age because of bilateral cryptorchidism. Notice the completely penile urethra; such complete masculinization in females with adrenal hyperplasia is rare; most of these infants have the salt-wasting form.

**PATHOGENESIS AND CLINICAL MANIFESTATIONS**

**Aldosterone and Cortisol Deficiency**

Because both cortisol and aldosterone require 21-hydroxylation for their synthesis, both hormones are deficient in the most-severe, salt-wasting form of the disease. This form constitutes approximately 70% of cases of classic 21-hydroxylase deficiency. The signs and symptoms of cortisol and aldosterone deficiency, and the pathophysiology underlying them, are essentially those described in Chapter 575. These include progressive weight loss, anorexia, vomiting, dehydration, weakness, hypotension, hypoglycemia, hypernatremia, and hyperkalemia. These problems typically first develop in affected infants at approximately 10-14 days of age. Without treatment, shock, cardiac arrhythmias, and death may occur within days or weeks.

CAH differs from other causes of primary adrenal insufficiency in that precursor steroids accumulate proximal to the blocked enzymatic conversion. Because cortisol is not synthesized efficiently, ACTH levels are high, leading to hyperplasia of the adrenal cortex and levels of precursor steroids that may be hundreds of times normal. In the case of 21-hydroxylase deficiency, these precursors include 17-hydroxyprogesterone and progesterone. Progesterone and perhaps other metabolites act as antagonists of the mineralocorticoid receptor and thus may exacerbate the effects of aldosterone deficiency in untreated patients.

**Prenatal Androgen Excess**

The most important problem caused by accumulation of steroid precursors is that 17-hydroxyprogesterone is shunted into the pathway for androgen biosynthesis, leading to high levels of androstenedione that are converted outside the adrenal gland to testosterone. This problem begins in affected fetuses by 8-10 wk of gestation and leads to abnormal genital development in females (see Figs. 576-1 and 576-2).

The external genitalia of males and females normally appear identical early in gestation (see Chapter 582). Affected females who are exposed in utero to high levels of androgens of adrenal origin have masculinized external genitalia (see Figs. 576-1 and 576-2). This is manifested by enlargement of the clitoris and by partial or complete labial fusion. The vagina usually has a common opening with the urethra (urogenital sinus). The clitoris may be so enlarged that it resembles a penis; because the urethra opens below this organ, some affected females may be mistaken for males with hypoplasia and cryptorchidism. The severity of virilization is usually greatest in females with the salt-losing form of 21-hydroxylase deficiency (see Table 576-2). The internal genital organs are normal, because affected females have normal ovaries and not testes and thus do not secrete antimüllerian hormone.

Prenatal exposure of the brain to high levels of androgens may influence subsequent sexually dimorphic behaviors in affected females. Girls may demonstrate aggressive play behavior, tend to be interested in masculine toys such as cars and trucks, and often show decreased interest in playing with dolls. Women may have decreased interest in maternal roles. There is an increased frequency of homosexuality in affected females. Nonetheless, most function heterosexually and do not have gender identity confusion or dysphoria. It is unusual for affected females to assign themselves a male role except in some with the severest degree of virilization.

Male infants appear normal at birth. Thus, the diagnosis may not be made in boys until signs of adrenal insufficiency develop. Because
patients with this condition can deteriorate quickly, infant boys are more likely to die than infant girls. For this reason, all 50 American states and many countries have instituted newborn screening for this condition (see "Newborn Screening" in Chapter 576.2).

**Postnatal Androgen Excess**
Untreated or inadequately treated children of both sexes develop additional signs of androgen excess after birth. Boys with the simple virilizing form of 21-hydroxylase deficiency often have a delayed diagnosis because they appear normal and rarely develop adrenal insufficiency.

Signs of androgen excess include rapid somatic growth and accelerated skeletal maturation. Thus, affected patients are tall in childhood but premature closure of the epiphyses causes growth to stop relatively early, and adult stature is stunted (see Fig. 576-1). Muscular development may be excessive. Pubic and axillary hair may appear, and acne and a deep voice may develop. The penis, scrotum, and prostate may become enlarged in affected boys; however, the testses are usually prepubertal in size so that they appear relatively small in contrast to the enlarged penis. Occasionally, ectopic adrenocortical cells in the testes of patients become hyperplastic similarly to the adrenal glands, producing testicular adrenal rest tumors (see Chapter 584). The clitoris may become further enlarged in affected females (see Fig. 576-1). Although the internal genital structures are female, breast development and menstruation may not occur unless the excessive production of androgens is suppressed by adequate treatment.

Similar but usually milder signs of androgen excess may occur in nonclassic 21-hydroxylase deficiency (see Table 576-2). In this attenuated form, cortisol and aldosterone levels are normal and affected females have normal genitals at birth. Males and females may present with precocious pubarche and early development of pubic and axillary hair. Hirsutism, acne, menstrual disorders, and infertility may develop later in life, but many females and males are completely asymptomatic.

**Adrenomedullary Dysfunction**
Development of the adrenal medulla requires exposure to the extremely high cortisol levels normally present within the adrenal gland. Thus patients with classic CAH have abnormal adrenomedullary function, as evidenced by blunted epinephrine responses, decreased blood glucose, and lower heart rates with exercise. Ability to exercise is unimpaired and the clinical significance of these findings is uncertain. Adrenomedullary dysfunction may exacerbate the cardiovascular effects of cortisol deficiency in untreated or undertreated patients.

**Laboratory Findings**
See Table 576-1.

Patients with salt-losing disease have typical laboratory findings associated with cortisol and aldosterone deficiency, including hypotension, hyperkalemia, metabolic acidosis, and, often, hypoglycemia, but these abnormalities can take 10-14 days or longer to develop after birth. Blood levels of 17-hydroxyprogesterone are markedly elevated. However, levels of this hormone are high during the 1st 2-3 days of life even in unaffected infants and especially if they are sick or premature. After infancy, once the circadian rhythm of cortisol is established, 17-hydroxyprogesterone levels vary in the same circadian pattern, being highest in the morning and lowest at night. Blood levels of cortisol are usually low in patients with the salt-losing type of disease. They are often normal in patients with simple virilizing disease but inappropriately low in relation to the ACTH and 17-hydroxyprogesterone levels. In addition to 17-hydroxyprogesterone, levels of androstenedione and testosterone are elevated in affected females; testosterone is not elevated in affected males, because normal infant males have high testosterone levels compared with those seen later in childhood. Levels of urinary 17-ketosteroids and pregnanetriol are elevated but are now rarely used clinically because blood samples are easier to obtain than 24 hr urine collections. ACTH levels are elevated but have no diagnostic utility over 17-hydroxyprogesterone levels. Plasma levels of renin are elevated, and serum aldosterone is inappropriately low for the renin level. However, renin levels are high in normal infants in the 1st few wk of life.

Diagnosis of 21-hydroxylase deficiency is most reliably established by measuring 17-hydroxyprogesterone before and 30 or 60 min after an intravenous bolus of 0.125-0.25 mg of cosyntropin (ACTH 1-24). Nomograms exist that readily distinguish normals and patients with nonclassic and classic 21-hydroxylase deficiency. Heterozygous carriers of this autosomal recessive disorder tend to have higher ACTH-stimulated 17-hydroxyprogesterone levels than genetically unaffected individuals, but there is significant overlap between subjects in these 2 categories. However, in infants with frank electrolyte abnormalities or circulatory instability, it may not be possible or necessary to delay treatment to perform this test, as levels of precursors will be sufficiently elevated on a random blood sample to make the diagnosis.

Genotyping is clinically available and may help confirm the diagnosis, but it is expensive and may take weeks. Because the gene conversions that generate most mutant alleles may transfer more than one mutation, at least one parent should be genotyped as well to determine which mutations lie on each allele.

**Differential Diagnosis**
Disorders of sexual development are discussed more generally in Chapter 588. The initial step in evaluating an infant with ambiguous genitals is a thorough physical examination to define the anatomy of the genitals, locate the urethral meatus, palpate the scrotum or labia and the inguinal regions for testes (palpable gonads almost always indicate the presence of testicular tissue and thus that the infant is a genetic male), and look for any other anatomic abnormalities. Ultrasonography is helpful in demonstrating the presence or absence of a uterus and can often locate the gonads. A rapid karyotype (such as fluorescence in situ hybridization of interphase nuclei for X and Y chromosomes) can quickly determine the genetic sex of the infant. These results are all likely to be available before the results of hormonal testing and together allow the clinical team to advise the parents as to the genetic sex of the infant and the anatomy of internal reproductive structures. Injection of contrast medium into the urogenital sinus of a virilized female demonstrates a vagina and uterus, and many surgeons utilize this information to formulate a plan for surgical management.

**Prenatal Diagnosis**
Prenatal diagnosis of 21-hydroxylase is possible late in the 1st trimester by analysis of DNA obtained by chorionic villus sampling or during the 2nd trimester by amniocentesis. This is usually done because the parents already have an affected child. Most often, the CYP21 gene is analyzed for frequently occurring mutations; more rare mutations may be detected by DNA sequencing.

**Newborn Screening**
Because 21-hydroxylase deficiency is often undiagnosed in affected males until they have severe adrenal insufficiency, all states in the United States and many other countries have instituted newborn screening programs. These programs analyze 17-hydroxyprogesterone levels in dried blood obtained by heelstick and absorbed on filter paper cards; the same cards are screened in parallel for other congenital conditions such as hypothyroidism and phenylketonuria. Potentially affected infants are typically quickly recalled for additional testing (electrolytes and repeat 17-hydroxyprogesterone determination) at approximately 2 wk of age. Infants with salt-wasting disease often have abnormal electrolytes by this age but are usually not severely ill. Thus, screening programs are effective in preventing many cases of adrenal crisis in affected males. The nonclassic form of the disease is not reliably detected by newborn screening, but this is of little clinical significance because adrenal insufficiency does not occur in this type of 21-hydroxylase deficiency.

The main difficulty with current newborn screening programs is that to reliably detect all affected infants, the cutoff 17-hydroxyprogesterone levels for recalls are set so low that there is a very high frequency of false-positive results (i.e., the test has a low positive predictive value
of approximately 1%). This problem is worst in premature infants. Positive predictive value can be improved by using cutoff levels based on gestational age, and by utilizing more specific second-tier screening methods such as liquid chromatography followed by tandem mass spectrometry.

**TREATMENT**

**Glucocorticoid Replacement**

Cortisol deficiency is treated with glucocorticoids. Treatment also suppresses excessive production of androgens by the adrenal cortex and thus minimizes problems such as excessive growth and skeletal maturation and virilization. This often requires larger glucocorticoid doses than are needed in other forms of adrenal insufficiency, typically 15-20 mg/m²/24 hr of hydrocortisone daily administered orally in 3 divided doses. Affected infants usually require dosing at the high end of this range. Double or triple doses are indicated during periods of stress, such as infection or surgery. Glucocorticoid treatment must be continued indefinitely in all patients with classic 21-hydroxylase deficiency but may not be necessary in patients with nonclassic disease unless signs of androgen excess are present. Therapy must be individualized. It is desirable to maintain linear growth along percentile lines; crossing to higher height percentiles may suggest undertreatment, whereas loss of height percentiles often indicates overtreatment with glucocorticoids. Overtreatment is also suggested by excessive weight gain. Pubertal development should be monitored by periodic examination, and skeletal maturation is evaluated by serial radiographs of the hand and wrist for bone age. Hormone levels, particularly 17-hydroxyprogesterone and androstenedione, should be measured early in the morning, before taking the morning medications, or at a consistent time in relation to medication dosing. In general, desirable 17-hydroxyprogesterone levels are in the high-normal range or several times normal; low-normal levels can usually be achieved only with excessive glucocorticoid doses.

Menarche occurs at the appropriate age in most girls in whom good control has been achieved; it may be delayed in girls with suboptimal control.

Children with simple virilizing disease, particularly males, are frequently not diagnosed until 3-7 yr of age, at which time skeletal maturation may be 5 yr or more in advance of chronological age. In some children, especially if the bone age is 12 yr or more, spontaneous central (i.e., gonadotropin-dependent) puberty may occur when treatment is instituted, because therapy with hydrocortisone suppresses production of adrenal androgens and thus stimulates release of pituitary gonadotropins if the appropriate level of hypotalamic maturation is present. This form of superimposed true precocious puberty may be treated with a gonadotropin hormone–releasing hormone analog such as leuprolide (see Chapter 562.1).

Males with 21-hydroxylase deficiency who have had inadequate corticosteroid therapy may develop testicular adrenal rest tumors, which usually regress with increased steroid dosage. Testicular MRI, ultrasonography, and color flow Doppler examination help define the character and extent of disease. Testis-sparing surgery for steroid-unresponsive tumors has been reported.

**Mineralocorticoid Replacement**

Patients with salt-wasting disease (i.e., aldosterone deficiency) require mineralocorticoid replacement with fludrocortisone. Infants may have very high mineralocorticoid requirements in the 1st few mo of life, usually 0.1-0.3 mg daily in 2 divided doses but occasionally up to 0.4 mg daily, and often require sodium supplementation (sodium chloride, 8 mmol/kg) in addition to the mineralocorticoid. Older infants and children are usually maintained with 0.05-0.1 mg daily of fludrocortisone. In some patients, simple virilizing disease may be easier to control with a low dose of fludrocortisone in addition to hydrocortisone even when these patients have normal aldosterone levels in the absence of mineralocorticoid replacement. Therapy is evaluated by monitoring of vital signs; tachycardia and hypertension are signs of overtreatment with mineralocorticoids. Serum electrolytes should be measured frequently in early infancy as therapy is adjusted. Plasma renin activity is a useful way to determine adequacy of therapy; it should be maintained in or near the normal range but not suppressed.

Additional approaches to improve outcome have been proposed but have not yet become the standard of care. These include an antiandrogen such as flutamide to block the effects of excessive androgen levels, and/or an aromatase inhibitor such as anastrozole, which blocks conversion of androgens to estrogen and thus retards skeletal maturation, a process that is sensitive to estrogens in both boys and girls. Aromatase inhibitors generally should not be used in pubertal girls because they will obviously retard normal puberty and may expose the ovaries to excessive levels of gonadotropins. Growth hormone, with or without luteinizing hormone–releasing hormone agonists to retard skeletal maturation, has been suggested to improve adult height.

**Surgical Management of Ambiguous Genitals**

Significantly virilized females usually undergo surgery between 2-6 mo of age. If there is severe clitoromegaly, the clitoris is reduced in size, with partial excision of the corporal bodies and preservation of the neurovascular bundle; however, moderate clitoromegaly may become much less noticeable even without surgery as the patient grows. Vaginoplasty and correction of the urogenital sinus usually are performed at the time of clitoral surgery; revision in adolescence is often necessary.

Risks and benefits of surgery should be fully discussed with parents of affected females. There is limited long-term follow-up of functional outcomes in patients who have undergone modern surgical procedures. It appears that female sexual dysfunction increases in frequency and severity in those with the most significant degrees of genital virilization and with the degree of enzymatic impairment (prenatal androgen exposure) caused by each patient’s mutations (see Table 576-2). Sex assignment of infants with disorders of sexual differentiation (including CAH) is usually based on expected sexual functioning and fertility in adulthood with early surgical correction of the external genitals to conform with the sex assignment. Confused gender identity is not uncommon with CAH; it occurs mostly in females with the salt-wasting form of the disease and the greatest degree of virilization.

Lay and medical opponents of genital surgery for other disorders of sexual differentiation state that it ignores any prenatally biased gender role predisposition from androgen exposure and precludes the patient from having any decision as to the patient’s own preferred sexual identity and what surgical correction of the genitals should be performed. These individuals and groups say treatment should be aimed primarily at educating the patient, family, and others about the medical condition, its treatment, and how to deal with the intersex condition. They propose that surgery should be delayed until the patient decides on what, if any, correction should be performed. Severely virilized genotypic (XX) females raised as males have generally functioned well in the male gender as adults.

In adolescent and adult females with poorly controlled 21-hydroxylase deficiency (hirsutism, obesity, amenorrhea), bilateral laparoscopic adrenalectomy (with hormone replacement) may be an alternative to standard medical hormone replacement therapy, but patients treated in this way may be more susceptible to acute adrenal insufficiency if treatment is interrupted because the adrenal glands have been removed. Moreover, they may exhibit signs of elevated ACTH levels such as abnormal pigmentation.

**Prenatal Treatment**

Besides genetic counseling, the main goal of prenatal treatment is to facilitate appropriate prenatal treatment of affected females. Mothers with pregnancies at risk are given dexamethasone, a steroid that readily crosses the placenta, in an amount of 20 µg/kg prepregnancy maternal weight daily in 2 or 3 divided doses. This suppresses secretion of steroids by the fetal adrenal, including secretion of adrenal androgens. If started by 6 wk of gestation, it ameliorates virilization of the external
Deficiency of 11β-hydroxysteroid dehydrogenase (3β-HSD) occurs in fewer than 2% of patients with adrenal hyperplasia. This enzyme is required for conversion of Δ5 steroids (pregnenolone, 17-hydroxypregnenolone, dehydroepiandrosterone [DHEA]) to Δ4 steroids (progesterone, 17-hydroxyprogesterone, and androstenedione). Thus, deficiency of the enzyme results in decreased synthesis of cortisol, aldosterone, and androstenedione but increased secretion of DHEA (see Fig. 574-1 in Chapter 574). The 3β-HSD isozyme expressed in the adrenal cortex and gonad is encoded by the HSD3B2 gene located on chromosome 1p13.1. Over 30 mutations in the HSD3B2 gene have been described in patients with 3β-HSD deficiency.

CLINICAL MANIFESTATIONS

Because cortisol and aldosterone are not synthesized in patients with the classic form of the disease, infants are prone to salt-wasting crises. Because androstenedione and testosterone are not synthesized, boys are incompletely virilized. Varying degrees of hypospadias may occur, with or without bifid scrotum or cryptorchidism. Because DHEA levels are elevated and this hormone is a weak androgen, girls are mildly virilized, with slight to moderate clitoral enlargement. Postnatally, continued excessive DHEA secretion can cause precocious adrenarche. During adolescence and adulthood, hirsutism, irregular menses, and polycystic ovarian disease occur in females. Males manifest variable degrees of hypogonadism, although appropriate male secondary sexual development may occur. A persistent defect of testicular 3β-HSD is demonstrated, however, by the high Δ5:Δ4 steroid ratio in testicular effluent.

LABORATORY FINDINGS

The hallmark of this disorder is the marked elevation of the Δ5 steroids (such as 17-hydroxyprogrenolone and DHEA) preceding the enzymatic block. Patients may also have elevated levels of 17-hydroxyprogesterone because of the extraglandular 3β-HSD activity that occurs in peripheral tissues; these patients may be mistaken for patients with 21-hydroxylase deficiency. The ratio of 17-hydroxyprogrenolone:17-hydroxyprogesterone is markedly elevated in 3β-HSD deficiency, in contrast to the decreased ratio in 21-hydroxylase deficiency. Plasma renin activity is elevated in the salt-wasting form.

DIFFERENTIAL DIAGNOSIS

It is not unusual for children with premature adrenarche, or women with signs of androgen excess, to have mild to moderate elevations in DHEA levels. It has been suggested that such individuals have "nonclassic 3β-HSD deficiency.” Mutations in the HSD3B2 gene are usually not found in such individuals, and a nonclassic form of this deficiency must actually be quite rare. The activity of 3β-HSD in the adrenal zonae...

fasciculata and reticularis, relative to CYP17 (17-hydroxylase/17,20-lyase) activity, normally decreases during adrenarche to facilitate DHEA synthesis, and so modest elevations in DHEA in preteenage children or women usually represent a normal variant.

TREATMENT

Patients require glucocorticoid and mineralocorticoid replacement with hydrocortisone and fludrocortisone, respectively, as in 21-hydroxylase deficiency. Incompletely virilized genetic males in whom a male sex of rearing is contemplated may benefit from several injections of 25 mg every 4 wk of a depot form of testosterone early in infancy to increase the size of the phallus. They may also require testosterone replacement at puberty.

Bibliography is available at Expert Consult.

576.4 Congenital Adrenal Hyperplasia Caused by 17-Hydroxylase Deficiency

ETIOLOGY

Less than 1% of CAH cases are caused by 17-hydroxylase deficiency, but the condition is apparently more common in Brazil and China. A single polypeptide, CYP17, catalyzes 2 distinct reactions: 17-hydroxylation of pregnenolone and progesterone to 17-hydroxyprogrenolone and 17-hydroxyprogesterone, respectively, and the 17,20-lyase reaction mediating conversion of 17-hydroxyprogrenolone to DHEA and, to a lesser extent, 17-hydroxyprogesterone to A4-androstenedione. DHEA and androstenedione are steroid precursors of testosterone and estrogen (see Fig. 574-1 in Chapter 574). The enzyme is expressed in both the adrenal cortex and the gonads and is encoded by a gene on chromosome 10q24.3. Most mutations affect both the hydroxylase and lyase activities, but rare mutations can affect either activity alone.

Mutations in genes other than CYP17 can have the same phenotype as 17,20-lyase deficiency (i.e., deficient androgen synthesis with normal cortisol synthesis). These include an accessory electron transfer protein, cytochrome b5, and mutations in 2 aldo-keto reductases, AKR1C2 and AKR1C4. These AKR1C isozymes normally catalyze 3α-hydroxysteroid dehydrogenase activity, which allows synthesis of the potent androgen dihydrotestosterone through an alternative “backdoor” biosynthetic pathway that does not include testosterone as an intermediate.

CLINICAL MANIFESTATIONS AND LABORATORY FINDINGS

Patients with 17-hydroxylase deficiency cannot synthesize cortisol, but their ability to synthesize corticosterone is intact. Because corticosterone is an active glucocorticoid, patients do not develop adrenal insufficiency. Deoxycorticosterone, the immediate precursor of corticosterone, is synthesized in excess. This can cause hypertension, hypokalemia, and suppression of renin and aldosterone secretion, as occurs in 11β-hydroxylase deficiency. In contrast to 11β-hydroxylase deficiency, patients with 17-hydroxylase deficiency are unable to synthesize sex hormones. Affected males are incompletely virilized and present as phenotypic females (but gonads are usually palpable in the inguinal region or the labia) or with sexual ambiguity. Affected females usually present with failure of sexual development at the expected time of puberty. 17-Hydroxylase deficiency in females must be considered in the differential diagnosis of primary hypogonadism (see Chapter 586). Levels of deoxycorticosterone are elevated and renin and aldosterone are consequently suppressed. Cortisol and sex steroids are unresponsive to stimulation with ACTH and human chorionic gonadotropin, respectively.

Patients with isolated 17,20-lyase deficiency have deficient androgen synthesis with normal cortisol synthesis, and therefore do not become hypertensive.

TREATMENT

Patients with 17-hydroxylase deficiency require cortisol replacement to suppress secretion of deoxycorticosterone and thus control hypertension. Additional antihypertensive medication may be required. Females require estrogen replacement at puberty. Genetic males may require either estrogen or androgen supplementation depending on the sex of rearing. Because of the possibility of malignant transformation of abdominal testes with androgen insensitivity syndrome (see Chapter 588.2), genetic males with severe 17-hydroxylase deficiency being reared as females require gonadectomy at or before adolescence.

576.5 Lipoid Adrenal Hyperplasia

Perrin C. White

ETIOLOGY

Lipoid adrenal hyperplasia is a rare disorder, most frequently found in Japanese persons. Patients with this disorder exhibit marked accumulation of cholesterol and lipids in the adrenal cortex and gonads, associated with severe impairment of all steroidogenesis. Lipoid adrenal hyperplasia is usually caused by mutations in the gene for steroidogenic acute regulatory protein (StAR), a mitochondrial protein that promotes the movement of cholesterol from the outer to the inner mitochondrial membrane. However, mutations in the CYP11A1 gene (which encodes the cholesterol side chain cleavage enzyme) have been reported in several patients.

Some cholesterol is able to enter mitochondria even in the absence of StAR, so it might be supposed that this disorder would not completely impair steroid biosynthesis. However, the accumulation of cholesterol in the cytoplasm is cytotoxic, eventually leading to death of all steroidogenic cells in which StAR is normally expressed. This occurs prenatally in the adrenals and testes. The ovaries do not normally synthesize steroids until puberty, so cholesterol does not accumulate and the ovaries can retain the capacity to synthesize estrogens until adolescence.

Although estrogens synthesized by the placenta are required to maintain pregnancy, the placenta does not require StAR for steroid biosynthesis. Thus, mutations of StAR are not prenatally lethal.

CLINICAL MANIFESTATIONS

Patients with lipoid adrenal hyperplasia are usually unable to synthesize any adrenal steroids. Thus, affected infants are likely to be confused with those with adrenal hypoplasia congenita. Salt-losing manifestations are typical, and many infants die in early infancy. Genetic males are unable to synthesize androgens and thus are phenotypically female but with gonads palpable in the labia majora or inguinal areas. Genetic females appear normal at birth and may undergo feminization at puberty with menstrual bleeding. They too, progress to hypergonadotropic hypogonadism when accumulated cholesterol kills granulosa (i.e., steroid synthesizing) cells in the ovary.

LABORATORY FINDINGS

Adrenal and gonadal steroid hormone levels are low in lipoid adrenal hyperplasia, with a decreased or absent response to stimulation (ACTH, human chorionic gonadotropin). Plasma renin levels are increased.

Imaging studies of the adrenal gland demonstrating massive adrenal enlargement in the newborn help establish the diagnosis of lipoid adrenal hyperplasia.

TREATMENT

Patients require glucocorticoid and mineralocorticoid replacement. Genetic males are usually assigned a female sex of rearing; thus both genetic males and females require estrogen replacement at the expected age of puberty.

576.6 Deficiency of P450 Oxidoreductase (Antley-Bixler Syndrome)

Perrin C. White

ETIOLOGY, PATHOGENESIS, AND CLINICAL MANIFESTATIONS

P450 oxidoreductase (POR, gene located on chromosome 7q11.3) is required for the activity of all microsomal cytochrome P450 enzymes (see Chapter 574) including the adrenal enzymes CYP17 and CYP21. Thus, complete POR deficiency abolishes all microsomal P450 activity. This is embryonically lethal in mice and presumably in humans as well. Patients with mutations that decrease but do not abolish POR activity have partial deficiencies of 17-hydroxylase and 21-hydroxylase activities in the adrenals. A single recurrent mutation, A287P (alanine-287 to proline) is found on approximately 40% of alleles.

Deficiency of 17-hydroxylase leads to incomplete masculinization in males; 21-hydroxylase deficiency may lead to virilization in females. Additionally, aromatase (CYP19) activity in the placenta is decreased, leading to unopposed action of androgens produced by the fetal adrenal. This exacerbates virilization of female fetuses and may virilize the mother of an affected fetus as well. Although it is puzzling that affected females could be virilized despite a partial deficiency in CYP17 (which is required for androgen biosynthesis), an alternative (“back-door”) biosynthetic pathway is utilized in which 17-hydroxyprogesterone is converted to 5α-pregnane-3α,17α-diol-20-one, a metabolite that is a much better substrate for the 17,20-lyase activity of CYP17 than the usual substrate, 17-hydroxyprogrenenolone (see Chapter 574). The metabolite is then converted in several enzymatic steps to dihydrotestosterone, a potent androgen.

Because many other P450 enzymes are affected, patients often (but not invariably) have other congenital anomalies collectively referred to as Antley-Bixler syndrome. These include craniosynostosis; brachycephaly; frontal bossing; severe midface hypoplasia with proptosis and choanal stenosis or atresia; humeroradial synostosis; medial bowing of ulnas; long, slender fingers with camptodactyly; narrow iliac wings; anterior bowing of femurs; and malformations of the heart and kidneys. Studies of mutant mice suggest that the metabolic defects responsible for these anomalies include defective metabolism of retinoic acid, leading to elevated levels of this teratogenic compound, and deficient biosynthesis of cholesterol.

EPIDEMIOLOGY

The prevalence is not known with certainty. It must be rare compared with 21-hydroxylase deficiency but might occur at similar frequencies to the other forms of CAH.

LABORATORY FINDINGS

Serum steroids that are not 17- or 21-hydroxylated are most increased, including pregnenolone and progesterone. 17-Hydroxy, 21-deoxysteroids are also increased, including 17-hydroxyprogrenenolone, 17-hydroxyprogesterone, and 21-deoxycorticisol. Urinary steroid metabolites may be determined by quantitative mass spectrometry. Metabolites excreted at increased levels include pregnanediol, pregnanetriol, pregnanetriolone, and corticosterone metabolites. Urinary cortisol metabolites are decreased. Genetic analysis demonstrates mutations in the POR gene.

DIFFERENTIAL DIAGNOSIS

This disorder must be distinguished from other forms of CAH, particularly 21-hydroxylase deficiency in females, which is far more common and has similar laboratory findings. Suspcion for POR deficiency may be raised if the mother is virilized or if the associated abnormalities of Antley-Bixler syndrome are present. Conversely, virilization of both the mother and her daughter can result from a luteoma of pregnancy, but in this case postnatal abnormalities of corticosteroid biosynthesis should not be observed. Antley-Bixler syndrome may also occur without abnormalities of steroid hormone biosynthesis, resulting from mutations in the fibroblast growth factor receptor FGFR2.

576.7 Aldosterone Synthase Deficiency

Perrin C. White

ETIOLOGY

This is a rare autosomal recessive disorder in which conversion of corticosterone to aldosterone is impaired; a group of Iranian Jewish patients has been the most thoroughly studied. The majority of cases result from mutations in the CYP11B2 gene coding for aldosterone synthase; however, linkage to CYP11B2 has been excluded in other kindreds. When not caused by CYP11B2 mutations, the disorder has been termed familial hyperreninemic hypoaldosteronism type 2; the causative gene or genes have not yet been identified.

Aldosterone synthase mediates the 3 final steps in the synthesis of aldosterone from deoxycorticosterone (11β-hydroxylation, 18-hydroxylation, and 18-oxidation). Although 11β-hydroxylation is required to convert deoxycorticosterone to corticosterone, this conversion can also be catalyzed by the related enzyme, CYP11B1, located in the fasciculata, which is unaffected in this disorder. For the same reason, these patients have normal cortisol biosynthesis.

The disease has been classified into 2 types, termed aldosterone methylxoxidase deficiency types I and II. They differ only in levels of the immediate precursor of aldosterone, 18-hydroxycorticosterone; levels are low in type I deficiency and elevated in type II deficiency. These differences do not correspond in a simple way to particular mutations and are of limited clinical importance.

CLINICAL MANIFESTATIONS

Infants with aldosterone synthase deficiency may have severe electrolyte abnormalities with hyponatremia, hyperkalemia, and metabolic acidosis. Because cortisol synthesis is unaffected, infants rarely become as ill as untreated infants with salt-losing forms of CAH such as 21-hydroxylase deficiency. Thus, some infants escape diagnosis. Later in infancy or in early childhood they may exhibit failure to thrive and poor growth. Adults often are asymptomatic, although they may develop electrolyte abnormalities when depleted of sodium through procedures such as bowel preparation for a barium enema.

LABORATORY FINDINGS

Infants have elevated plasma renin activity. Aldosterone levels are decreased; they may be at the lower end of the normal range but are always inappropriately low for the degree of hyperkalemia or hyperreninemia. Corticosterone levels are often elevated.

Some, but not all, patients have marked elevation of 18-hydroxycorticosterone; however, low levels of this steroid do not exclude the diagnosis. In those kindreds in which 18-hydroxycorticosterone levels are elevated in affected individuals, this biochemical abnormality persists in adults even when they have no electrolyte abnormalities.

DIFFERENTIAL DIAGNOSIS

It is important to distinguish aldosterone synthase deficiency from primary adrenal insufficiency in which both cortisol and aldosterone are affected (including salt-wasting forms of CAH) because the latter condition is usually associated with a much greater risk of shock and hyponatremia. This becomes apparent after the appropriate laboratory studies. Adrenal hypoplasia congenita may initially present with aldosterone deficiency; all male infants with apparently isolated aldosterone deficiency should be carefully monitored for subsequent development of cortisol deficiency. Pseudohypoaldosteronism (see Chapter 575.4) may have similar electrolyte abnormalities and
Bibliography

hyperreninemia, but aldosterone levels are high, and this condition usually does not respond to fludrocortisone treatment.

**TREATMENT**

Treatment consists of giving enough fludrocortisone (0.05-0.3 mg daily) or sodium chloride, or both, to return plasma renin levels to normal. With increasing age, salt-losing signs usually improve and drug therapy can often be discontinued.

Bibliography is available at Expert Consult.

**576.8 Glucocorticoid-Suppressible Hyperaldosteronism**

*Perrin C. White*

---

**ETIOLOGY**

Glucocorticoid-suppressible hyperaldosteronism (glucocorticoid-remediable aldosteronism, familial hyperaldosteronism type I) is an autosomal dominant form of low-renin hypertension in which hyperaldosteronism is rapidly suppressed by glucocorticoid administration. This unusual effect of glucocorticoids suggests that aldosterone secretion in this disorder is regulated by ACTH instead of by the renin–angiotensin system. In addition to abnormally regulated secretion of aldosterone, there is marked overproduction of 18-hydroxycortisol and 18-oxocortisol. The synthesis of these steroids requires both 17-hydroxylase (CYP17) activity, which is expressed only in the zona fasciculata, and aldosterone synthase (CYP11B2) activity, which is normally expressed only in the zona glomerulosa. Together, these features imply that aldosterone synthase is being expressed in a manner similar to the closely related enzyme steroid 11-hydroxylase (CYP11B1). The disorder is caused by unequal meiotic crossing-over events between the *CYP11B1* and *CYP11B2* genes, which are closely linked on chromosome 8q24. An additional "hybrid" gene is produced, having regulatory sequences of *CYP11B1* juxtaposed with coding sequences of *CYP11B2*. This results in the inappropriate expression of a *CYP11B2*-like enzyme with aldosterone synthase activity in the adrenal fasciculata.

**CLINICAL MANIFESTATIONS**

Some affected children have no symptoms, the diagnosis being established after incidental discovery of moderate hypertension, typically approximately 30 mm Hg higher than unaffected family members of the same age. Others have more symptomatic hypertension with headache, dizziness, and visual disturbances. A strong family history of early-onset hypertension or early strokes may alert the clinician to the diagnosis. Some patients have chronic hypokalemia, but this is not a consistent finding and is usually mild.

**LABORATORY FINDINGS**

Patients have elevated plasma and urine levels of aldosterone and suppressed plasma renin activity. Hypokalemia is not consistently present. Urinary and plasma levels of 18-oxocortisol and 18-hydroxy cortisol are markedly increased. The hybrid *CYP11B1/CYP11B2* gene can be readily detected by molecular genetic methods.

**DIFFERENTIAL DIAGNOSIS**

This condition should be distinguished from primary aldosteronism based on bilateral hyperplasia or an aldosterone-producing adenoma (see Chapter 578). Most cases of primary aldosteronism are sporadic, although several affected kindreds have been reported. Patients with primary aldosteronism may also have elevated levels of 18-hydroxycortisol and 18-oxocortisol, and these biochemical tests should be used cautiously to distinguish primary and glucocorticoid-suppressible aldosteronism. A therapeutic trial of dexamethasone may be helpful if aldosterone secretion is suppressed, and genetic testing should identify the hybrid gene of glucocorticoid-suppressible hyperaldosteronism if it is present.
Bibliography

Bibliography

Cushing syndrome is the result of abnormally high blood levels of cortisol or other glucocorticoids. This can be iatrogenic or the result of endogenous cortisol secretion, a result of either an adrenal tumor or of hypersecretion of corticotropin (adrenocorticotropic hormone [ACTH]) by the pituitary (Cushing disease) or by a tumor (Table 577-1).

**ETIOLOGY**

The most common cause of Cushing syndrome is prolonged exogenous administration of glucocorticoid hormones, especially at the high doses used to treat lymphoproliferative disorders. This rarely represents a diagnostic challenge, but management of hyperglycemia, hypertension, weight gain, linear growth retardation, and osteoporosis often complicates therapy with corticosteroids.

**Endogenous Cushing syndrome** is most often caused in infants by a functioning adrenocortical tumor (see Chapter 579). Patients with these tumors often exhibit signs of hypercortisolism along with signs of hypersecretion of other steroids such as androgens, estrogens, and aldosterone.

Although extremely rare in infants, the most common etiology of endogenous Cushing syndrome in children older than 7 yr of age is **Cushing disease**, in which excessive ACTH secreted by a pituitary adenoma causes bilateral adrenal hyperplasia. Such adenomas are often too small to detect by imaging techniques and are termed microadenomas. They consist principally of chromophobe cells and frequently show positive immunostaining for ACTH and its precursor, proopiomelanocortin. Whereas the vast majority of such tumors are sporadic, a small number occur in kindreds with familial isolated pituitary adenoma syndrome. This syndrome, which is caused by mutations in the aryl hydrocarbon receptor interacting protein (*AIP*) gene, accounts for perhaps 2% of pituitary adenomas, but more commonly tumors with *AIP* mutations secrete growth hormone or prolactin, and only rarely do they secrete ACTH. Similarly, multiple endocrine neoplasia type 1 (MEN1) patients, who by definition have mutations in the MEN1 (menin) gene, may develop pituitary tumors, but these are typically prolactinomas.

**ACTH-dependent Cushing syndrome** may also result from ectopic production of ACTH, although this is uncommon in children. Ectopic

ACTH secretion in children is associated with islet cell carcinoma of the pancreas, neuroblastoma or ganglioneuroblastoma, hemangiopericytoma, Wilms tumor, and thymic carcinoid. Hypertension is more common in the ectopic ACTH syndrome than in other forms of Cushing syndrome, because very high cortisol levels may overwhelm 11β-hydroxysteroid dehydrogenase in the kidney (see Chapter 575) and thus have an enhanced mineralocorticoid (salt-retaining) effect.

Several syndromes are associated with the development of multiple autonomously hyperfunctioning nodules of adrenocortical tissue, rather than single adenomas or carcinomas (which are discussed in Chapter 579). Primary pigmented nodular adrenocortical disease (PPNAD) is a distinctive form of ACTH-independent Cushing syndrome. It may occur as an isolated event or, more commonly, as a familial disorder with other manifestations. The adrenal glands are small and have characteristic multiple, small (<4 mm in diameter), pigmented (black) nodules containing large cells with cytoplasm and lipofuscin; there is cortical atrophy between the nodules. This adrenal disorder occurs as a component of Carney complex, an autosomal dominant disorder also consisting of centrofacial lentigines and blue nevi; cardiac and cutaneous myxomas; pituitary, thyroid, and testicular tumors; and pigmented melanotic schwannomas. Carney complex is inherited in an autosomal dominant manner, although sporadic cases occur. Genetic loci for Carney complex have been mapped to the gene for the type 1α regulatory subunit of protein kinase A (PRKAR1A) on chromosome 17q22-24 and less frequently to chromosome 2p16. Patients with Carney complex and PRKAR1A mutations generally develop PPNAD as adults, and those with the disorder mapping to chromosome 2 (and most sporadic cases) develop PPNAD less frequently and later. Conversely, children presenting with PPNAD as an isolated finding rarely have mutations in PRKAR1A, or subsequently develop other manifestations of Carney complex. Some patients with isolated PPNAD have mutations in the PDE8B or PDE11A genes encoding different phosphodiesterase isozymes.

ACTH-independent Cushing syndrome with nodular hyperplasia and adenoma formation occurs rarely in cases of McCune-Albright syndrome, with symptoms beginning in infancy or childhood. McCune-Albright syndrome is caused by a somatic mutation of the GNAS gene encoding the G protein, Gα, through which the ACTH receptor (MCR2) normally signals. This results in inhibition of guanosine triphosphatase activity and constitutive activation of adenylate cyclase, thus increasing levels of cyclic adenosine monophosphate. When the mutation is present in adrenal tissue, cortisol and cell division are stimulated independently of ACTH. Other tissues in which activating mutations may occur are bone (producing fibrous dysplasia), gonads, thyroid, and pituitary. Clinical manifestations depend on which tissues are affected.

Thus the genes causing nodular adrenocortical hyperplasia that have been identified thus far all produce overactivity of the ACTH signaling pathway either by constitutively activating Gα (McCune-Albright syndrome), by reducing the breakdown of cyclic adenosine monophosphate and thus increasing its intracellular levels (mutations of PDE8B or PDE11A), or by disrupting the regulation of the cyclic adenosine monophosphate–dependent enzyme, protein kinase A (PRKAR1A mutations).

Additionally, adrenocortical lesions including diffuse hyperplasia, nodular hyperplasia, adenoma, and rarely carcinoma may occur as part of the MEN1 syndrome (see Chapter 573), an autosomal dominant disorder, in which there is homozygous inactivation of the menin (MEN1) tumor-suppressor gene on chromosome 11q13.

CLINICAL MANIFESTATIONS

Signs of Cushing syndrome have been recognized in infants younger than 1 yr of age. The disorder appears to be more severe and the clinical findings more flagrant in infants than in older children. The face is rounded, with prominent cheeks and a flushed appearance (moon facies). Generalized obesity is common in younger children. In children with adrenal tumors, signs of abnormal masculinization occur frequently; accordingly, there may be hirsutism on the face and trunk, pubic hair, acne, deepening of the voice, and enlargement of the clitoris in girls. Growth is impaired, with length falling below the 3rd percentile, except when significant virilization produces normal or even accelerated growth. Hypertension is common and may occasionally lead to heart failure. An increased susceptibility to infection may also lead to sepsis.

In older children, in addition to obesity, short stature is a common presenting feature. Gradual onset of obesity and deceleration or cessation of growth may be the only early manifestations. Older children most often have more severe obesity of the face and trunk compared with the extremities. Purplish striae on the hips, abdomen, and thighs are common. Pubertal development may be delayed, or amenorrhea may occur in girls past menarche. Weakness, headache, and emotional lability may be prominent. Hypertension and hyperglycemia usually occur; hyperglycemia may progress to frank diabetes. Osteoporosis is common and may cause pathologic fractures.

LABORATORY FINDINGS

Cortisol levels in blood are normally highest at 8 AM and decrease to less than 50% by midnight except in infants and young children in whom a diurnal rhythm is not always established. In patients with Cushing syndrome this circadian rhythm is lost; midnight cortisol levels >4.4 μg/dL strongly suggest the diagnosis. It is difficult to obtain diurnal blood samples as part of an outpatient evaluation, but cortisol can be measured in saliva samples, which can be obtained at home at the appropriate times of day. Elevated nighttime salivary cortisol levels raise suspicion for Cushing syndrome.

Urinary excretion of free cortisol is increased. This is best measured in a 24 hr urine sample and is expressed as a ratio of micrograms of cortisol excreted per gram of creatinine. This ratio is independent of body size and completeness of the urine collection.
**DIFFERENTIAL DIAGNOSIS**

Cushing syndrome is frequently suspected in children with obesity, particularly when striae and hypertension are present. Children with simple obesity are usually tall, whereas those with Cushing syndrome are short or have a decelerating growth rate. Although urinary excretion of cortisol is often elevated in simple obesity, salivary nighttime levels of cortisol are usually normal and cortisol secretion is suppressed by oral administration of low doses of dexamethasone.

Elevated levels of cortisol and ACTH without clinical evidence of Cushing syndrome occur in patients with generalized glucocorticoid resistance (see Chapter 575.4). Affected patients may be asymptomatic or exhibit hypertension, hypokalemia, and precocious pseudopuberty; these manifestations are caused by increased mineralocorticoid and adrenal androgen secretion in response to elevated ACTH levels. Mutations in the glucocorticoid receptor have been identified.

**TREATMENT**

Transsphenoidal pituitary microsurgery is the treatment of choice in pituitary Cushing disease in children. The overall success rate with follow-up of less than 10 yr is 60-80%. Low postoperative serum or urinary cortisol concentrations predict long-term remission in the majority of cases. Relapses are treated with reoperation or pituitary irradiation.

Cyproheptadine, a centrally acting serotonin antagonist that blocks ACTH release, has been used to treat Cushing disease in adults; remissions are usually not sustained after discontinuation of therapy. This agent is rarely used in children. Inhibitors of adrenal steroidogenesis (metyrapone, ketoconazole, aminogluthethimide, etomidate) have been used preoperatively to normalize circulating cortisol levels and reduce perioperative morbidity and mortality. Mifepristone, a glucocorticoid receptor antagonist, has been used in a limited number of cases.
Bibliography

Primary aldosteronism encompasses disorders caused by excessive aldosterone secretion independent of the renin–angiotensin system. These disorders are characterized by hypertension, hypokalemia, and suppression of the renin–angiotensin system.

**ETIOLOGY**

Aldosterone-secreting adenomas are unilateral and have been reported in children as young as 3.5 yr of age; they mainly affect girls. Adrenocortical tumors are discussed further in Chapter 579. Bilateral micronodular adrenocortical hyperplasia tends to occur in older children and is more frequent in males. Primary aldosteronism due to unilateral adrenal hyperplasia may also occur. Glucocorticoid-suppressible hyperaldosteronism is discussed in Chapter 576.8.

**EPIDEMIOLOGY**

These conditions are thought to be rare in children, but they may account for 5-10% of cases of hypertension in adults. Although usually sporadic, kindreds with several affected members have been reported. Genetic linkage to chromosome 7p22 has been identified in some of these kindreds, but the involved gene has not yet been identified. Mutations in the KCNJ5 gene on chromosome 11q24 have been identified in several kindreds; these mutations (G151R and G151E) altered channel selectivity, producing increased Na⁺ conductance and membrane depolarization, which increases aldosterone production and proliferation of adrenal glomerulosa cells. Moreover, such mutations have been identified in a subset of sporadic aldosterone-producing adenomas.
CLINICAL MANIFESTATIONS
Some affected children have no symptoms, the diagnosis being established after incidental discovery of moderate hypertension. Others have severe hypertension (up to 240/150 mm Hg), with headache, dizziness, and visual disturbances. Chronic hypokalemia, if present, may lead to polyuria, nocturia, enuresis, and polydipsia. Muscle weakness and discomfort, tetany, intermittent paralysis, fatigue, and growth failure affect children with severe hypokalemia.

LABORATORY FINDINGS
Hypokalemia occurs frequently. Serum pH and the carbon dioxide and sodium concentrations may be elevated and the serum chloride and magnesium levels decreased. Serum levels of calcium are normal, even in children who manifest tetany. The urine is neutral or alkaline, and urinary potassium excretion is high. Plasma levels of aldosterone may be normal or elevated. Aldosterone concentrations in 24 hr urine collections are always increased. Plasma levels of renin are persistently low.

The diagnostic test of choice for primary aldosteronism is controversial. Both renin and aldosterone levels may vary by time of day, posture, and sodium intake, making it difficult to establish consistent reference ranges. It is desirable to establish a consistent sampling protocol, for example, at midmorning after the patient has been sitting for 15 min. If possible, antihypertensive drugs or other medications that can affect aldosterone or renin secretion should be avoided for several weeks prior to testing, including diuretics, β-blockers, angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, clonidine, and nonsteroidal antiinflammatory agents. Patients taking these agents may need to be changed to α-adrenergic blockers or calcium channel blockers that have smaller effects on the biochemical measurements. The ratio of plasma aldosterone concentration to renin activity is always high, and this represents a cost-effective screening test for primary aldosteronism. Aldosterone does not decrease with administration of saline solution or fludrocortisone, and renin does not respond to salt and fluid restriction. Urinary and plasma levels of 18-oxocortisol and 18-hydroxycortisol may be increased but not to the extent seen in glucocorticoid-suppressible hyperaldosteronism.

DIFFERENTIAL DIAGNOSIS
Primary aldosteronism should be distinguished from glucocorticoid-suppressible hyperaldosteronism (see Chapter 576.8), which is specifically treated with glucocorticoids. An autosomal dominant pattern of inheritance should raise suspicion for the latter disorder. Glucocorticoid-suppressible hyperaldosteronism is diagnosed by dexamethasone suppression tests or by specific genetic testing. More generally, primary aldosteronism should be distinguished from other forms of hypertension by means of the testing previously discussed.

TREATMENT
The treatment of an aldosterone-producing adenoma is surgical removal. This is performed primarily by laparotomy and adrenalectomy; successful enucleation of aldosterone-producing adenomas, as well as laparoscopic adrenalectomy, has been reported. Hyperaldosteronism caused by bilateral adrenal hyperplasia is treated with the mineralocorticoid antagonists spironolactone (1-3 mg/kg/day to a maximum of 100 mg/day) or eplerenone (25-100 mg/day in 2 divided doses), often normalizing blood pressure and serum potassium levels. There is greater experience with spironolactone, but this agent has antiandrogenic properties that may be unacceptable in pubertal males. Eplerenone is a more specific antimineralocorticoid that is safe in children, but there is little specific experience with primary aldosteronism in the pediatric age group. As an alternative, an epithelial sodium channel blocker, such as amiloride, may be used, with other antihypertensive agents added as necessary. In patients whose condition cannot be controlled medically, unilateral adrenalectomy may be considered.

Bibliography is available at Expert Consult.
Bibliography
EPIDEMIOLOGY
Adrenocortical tumors are rare in childhood, with an incidence of 0.3-0.5 cases per 1 million child-years. They occur in all age groups but most commonly in children younger than 6 yr of age, and are more frequent (1.6-fold) in girls. In 2-10% of cases, the tumors are bilateral. Almost half of childhood adrenocortical tumors are carcinomas.

Symptoms of endocrine hyperfunction are present in 80-90% of children with adrenal tumors (see Table 577-1 in Chapter 577). Tumors that secrete cortisol and aldosterone are also discussed in Chapters 577 and 578, respectively. Tumors may be associated with hemihypertrophy, usually occurring during the 1st few yr of life. They are also associated with other congenital defects, particularly genitourinary tract and central nervous system abnormalities and hamartomatous defects.

ETIOLOGY
The incidence of adrenocortical tumors is increased in several familial cancer syndromes resulting from abnormalities in genes that encode transcription factors implicated in cell proliferation, differentiation, senescence, apoptosis, and genomic instability. These include tumor protein 53 (TP53), menin (the MEN1 gene involved in multiple endocrine neoplasia type 1), the APC gene involved in familial adenomatous polyposis colo, and the PRKAR1A gene encoding a cyclic adenosine monophosphate–dependent protein kinase regulatory subunit (also see Chapter 577).

Germline mutations in TP53 (on chromosome 17p13.1) have been found in patients with isolated adrenal carcinoma as well as in patients with familial clustering of unusual malignancies; this latter condition is termed Li-Fraumeni syndrome. A 15-fold increased incidence of childhood adrenocortical tumors is found in southern Brazil, associated with a R337H mutation in TP53. Overexpression of insulin-like growth factor 2 (encoded by IGF2, on chromosome 11p15.5) occurs in 80% of sporadic childhood adrenocortical tumors, as well as in those associated with Beckwith-Wiedemann syndrome, in which there is loss of the normal imprinting of genes in this chromosomal region. Further implicating insulin-like growth factors (IGFs) in pathogenesis, many pediatric adrenocortical tumors overexpress the IGF receptor, IGF1R. Overexpression of steroidogenic factor-1 (SF1), a transcription factor required for adrenal development (see Chapter 574) is associated with decreased overall survival and recurrence-free survival when it occurs in adults with adrenocortical carcinomas, but it is seen in most pediatric adrenocortical tumors, where it does not seem to have prognostic significance. Conversely, the messenger RNA encoding the nephroblastoma overexpressed (NOV) protein (also termed cysteine-rich protein 61, or connective tissue growth factor, or nephroblastoma overexpressed gene-3) is significantly downregulated in childhood adrenocortical tumors. NOV is a selective proapoptotic factor for human adrenocortical cells, suggesting that abnormal apoptosis may play a role in childhood adrenocortical tumorigenesis.

Aldosterone-producing adenomas constitute a separate category from other adrenocortical tumors. They are very rarely malignant. The majority have mutations that activate the Wnt/β-catenin signaling pathway, either in β-catenin itself, or in the APC gene, which regulates this pathway. Additional, somatic mutations are often found in the potassium channel, KCNJ5, which probably first causes cell hypertrophy (see Chapter 576.8).
579.1 Virilizing and Feminizing Adrenal Tumors
Perrin C. White

CLINICAL MANIFESTATIONS
Virilization is the most common presenting symptom in children with adrenocortical tumors, occurring in 50-80%. In males, the clinical picture is similar to that of simple virilizing congenital adrenal hyperplasia: accelerated growth velocity and muscle development, acne, penile enlargement, and the precocious development of pubic and axillary hair. In females, virilizing tumors of the adrenal gland cause masculinization of a previously normal female with clitoral enlargement, growth acceleration, acne, deepening of the voice, and premature pubic and axillary hair development.

Conversely, adrenal tumors can occasionally (less than 10%) secrete high levels of estrogens as a result of overexpression of CYP19 (aromatase). Gynecomastia in males or premature thelarche in girls is often the initial manifestation. Growth and development may be otherwise normal, or concomitant virilization may occur.

In addition to virilization, 15-40% of children with adrenocortical tumors also have Cushing syndrome (see Chapter 577). Whereas isolated virilization occurs relatively frequently, children with adrenal tumors usually do not have Cushing syndrome alone.

In adults, adrenal tumors are frequently detected incident to CT or MRI imaging of the abdomen for other reasons; these are often referred to as incidentalomas (see Chapter 581.1). There are no published data on the frequency of the occurrence of such tumors in childhood. They are likely to be infrequent, being found in approximately 7% of autopsies of persons older than age 70 yr but in <1% of those younger than age 30 yr.

LABORATORY FINDINGS
Serum levels of dehydroepiandrosterone, dehydroepiandrosterone sulfate, and androstenedione are usually elevated, often markedly. Serum levels of testosterone are often increased, usually as a result of peripheral conversion of androstenedione, but infants with predominantly testosterone-secreting adenomas have been reported. Levels of estrone and estradiol are elevated in tumors from patients with feminizing signs. Urinary 17-ketosteroids (sex steroid metabolites) are also increased but are no longer routinely measured. Many adrenocortical tumors have a relative deficiency of 11β-hydroxylase activity and secrete increased amounts of deoxycorticosterone; these patients are hypertensive, and their tumors are often malignant.

Tumors can usually be detected by ultrasonography, CT, or MRI. Preoperatively, the presence of metastatic disease should be determined by MRI or CT of the chest, abdomen, and pelvis. Radiochemical imaging of these tumors by positron emission tomography with 11C-metomidate or single photon emission CT with 123I-iodometomidate have been proposed but are not routinely available.

PATHOLOGIC FINDINGS
Differentiation between benign and malignant tumors by histologic criteria (architecture, cytologic atypia, mitotic activity, atypical mitotic figures) is usually not possible; almost all pediatric adrenocortical tumors would be classified as malignant by the criteria used to classify adult tumors. Size is a useful prognostic factor, with tumors weighing less than 200 g, 200-400 g, and >400 g being classified as low, intermediate, and high risk (>10 cm diameter has also been suggested as a high-risk category). Incomplete resection and gross local invasion or metastasis are also associated with a poor prognosis. However, most tumors occurring in children younger than 4 yr of age fall into favorable prognostic categories.

DIFFERENTIAL DIAGNOSIS
For functioning tumors, the differential diagnoses are those of the main presenting signs and symptoms. The differential diagnosis for Cushing syndrome is discussed in Chapter 577. For virilizing signs, the differential includes virilizing forms of adrenal hyperplasia (see Chapter 576) and factitious exposure to androgens, such as topical testosterone preparations. The differential diagnosis for hormonally inactive adrenocortical adenomas includes pheochromocytomas, adrenocortical carcinoma, and metastasis from an extraadrenal primary carcinoma (very rare in children). Careful history, physical examination, and endocrine evaluation must be performed to seek evidence of autonomous cortisol, androgen, mineralocorticoid, or catecholamine secretion. Not infrequently, a low level of autonomous cortisol secretion is detected that does not cause clinically apparent symptoms; this condition is sometimes referred to as “subclinical” Cushing syndrome.

TREATMENT
Functioning adrenocortical tumors should be removed surgically. There are no data on which to base a recommendation regarding nonfunctioning childhood incidentalomas; in adults, such tumors may be closely observed with imaging and repeat biochemical studies if smaller than 4 cm in diameter, but it is not certain that this is prudent in small children. Adrenalectomy may be performed either transperitoneally or laparoscopically. Some adrenocortical neoplasms are highly malignant and metastasize widely, but cure with regression of masculinizing or Cushingoid features may follow removal of less malignant, encapsulated tumors. Postoperatively, patients should be closely monitored biochemically, with frequent determinations of adrenal androgen levels and imaging studies. Recurrent symptoms or biochemical abnormalities should prompt a careful search for metastatic disease. Metastases primarily involve liver, lung, and regional lymph nodes. The majority of metastatic recurrences appear within 1 yr of tumor resection. Repeat surgical resection of metastatic lesions should be performed if possible and adjuvant therapy instituted. Radiation therapy has not been generally helpful. Antineoplastic agents such as cisplatin and etoposide, ifosfamide and carboplatin, and 5-fluorouracil and levorcorvin have had limited use in children, and their success is not established. Therapy with o,p'-DDD (mitotane), an adrenolytic agent, may relieve the symptoms of hypercortisolism or virilization in recurrent disease. Treatment with higher doses of mitotane for more than 6 mo is associated with improved survival. Other agents that interfere with adrenal steroid synthesis, such as ketoconazole, aminoglutethimide, and metyrapone, may also relieve symptoms of steroid excess but do not improve survival.

A neoplasm of 1 adrenal gland may produce atrophy of the other because excessive production of cortisol by the tumor suppresses adrenocorticotropic hormone stimulation of the normal gland. Consequently, adrenal insufficiency may follow surgical removal of the tumor. This situation can be avoided by giving 10-25 mg of hydrocortisone every 6 hr, starting on the day of operation and weaned over 3-4 days postoperatively. Adequate quantities of water, sodium chloride, and glucose also must be provided.

Bibliography is available at Expert Consult.
Bibliography

Pheochromocytomas are catecholamine-secreting tumors arising from chromaffin cells. The most common site of origin (approximately 90%) is the adrenal medulla; however, tumors may develop anywhere along the abdominal sympathetic chain and are likely to be located near the aorta at the level of the inferior mesenteric artery or at its bifurcation.
They also appear in the periadrenal area, urinary bladder or ureteral walls, thoracic cavity, and cervical region. Ten percent occur in children, in whom they present most frequently between 6 and 14 yr of age. Tumors vary from 1-10 cm in diameter; they are found more often on the right side than on the left. In more than 20% of affected children, the adrenal tumors are bilateral; in 30-40% of children, tumors are found in both adrenal and extraadrenal areas or only in an extraadrenal area.

**ETIOLOGY**

Pheochromocytomas may be associated with genetic syndromes such as von Hippel-Lindau disease, as a component of multiple endocrine neoplasia (MEN) syndromes MEN2A and MEN2B, and more rarely in association with neurofibromatosis (type 1) or tuberous sclerosis. The classic features of von Hippel-Landau syndrome, which occurs in 1 in 36,000 individuals, include retinal and central nervous system hemangioblastomas, renal clear cell carcinomas, and pheochromocytomas, but kindreds differ in their propensity to develop pheochromocytoma; in some kindreds, pheochromocytoma is the only tumor to develop. Germline mutations in the VHL tumor-suppressor gene on chromosome 3p25-26 have been identified in patients with this syndrome. Mutations of the RET protooncogene on chromosome 10q11.2 have been found in families with MEN2A and MEN2B. Patients with MEN2 are at risk of developing medullary thyroid carcinoma and parathyroid tumors; approximately 50% develop pheochromocytoma, with patients carrying mutations at codon 634 of the RET gene being at particularly high risk. Mutations are present in the NFI gene on chromosome 17q11.2 in neurofibromatosis type 1 patients.

Pheochromocytomas may occur in kindreds along with paragangliomas, particularly at sites in the head and neck. Such families typically carry mutations in the SDHB, SDHD, and, rarely, the SDHC genes encoding subunits of the mitochondrial enzyme succinate dehydrogenase.

Pheochromocytomas are also associated with tuberous sclerosis, Sturge-Weber syndrome, and ataxia-telangiectasia. Somatic mutations of the genes mentioned above, particularly VHL, have been found in some sporadic cases of pheochromocytoma (see Chapter 596).

**CLINICAL MANIFESTATIONS**

Pheochromocytomas detected by surveillance of patients who are known carriers of mutations in tumor-suppressor genes may be asymptomatic. Otherwise, patients are detected owing to hypertension, which results from excessive secretion of epinephrine and norepinephrine. All patients have hypertension at some time. Paroxysmal hypertension should particularly suggest pheochromocytoma as a diagnostic possibility, but in contrast to adults, the hypertension in children is more often sustained rather than paroxysmal. When there are paroxysms of hypertension, the attacks are usually infrequent at first, but become more frequent and eventually give way to a continuous hypertensive state. Between attacks of hypertension, the patient may be free of symptoms. During attacks, the patient complains of headache, palpitations, abdominal pain, and dizziness; pallor, vomiting, and sweating also occur. Convulsions and other manifestations of hypertensive encephalopathy may occur. In severe cases, precordial pains radiate into the arms; pulmonary edema and cardiac and hepatic enlargement may develop. Symptoms may be exacerbated by exercise, or with use of nonprescription medications containing stimulants such as pseudoephedrine. Patients have a good appetite but because of the hypermetabolic state may not gain weight, and severe cachexia may develop. Polyuria and polydipsia can be sufficiently severe to suggest diabetes insipidus. Growth failure may be striking. The blood pressure may range from 180-260 mm Hg systolic and from 120-210 mm Hg diastolic, and the heart may be enlarged. Ophthalmoscopic examination may reveal papilledema, hemorrhages, exudate, and arterial constriction.

**LABORATORY FINDINGS**

The urine may contain protein, a few casts, and occasionally glucose. Gross hematuria suggests that the tumor is in the bladder wall. Polycythemia is occasionally observed. The diagnosis is established by demonstration of elevated blood or urinary levels of catecholamines and their metabolites.

Pheochromocytomas produce norepinephrine and epinephrine. Normally, norepinephrine in plasma is derived from both the adrenal gland and adrenergic nerve endings, whereas epinephrine is derived primarily from the adrenal gland. In contrast to adults with pheochromocytoma in whom both norepinephrine and epinephrine are elevated, children with pheochromocytoma predominantly excrete norepinephrine in the urine. Total urinary catecholamine excretion usually exceeds 300 µg/24 hr. Urinary excretion of metanephrines (particularly normetanephrine) is also increased (see Fig. 574-3 in Chapter 574). Daily urinary excretion of these compounds by unaffected children increases with age. Although urinary excretion of vanillylmandelic acid (3-methoxy-4-hydroxymandelic acid), the major metabolite of epinephrine and norepinephrine, is increased, vanilla-containing foods and fruits can produce falsely elevated levels of this compound, which therefore is no longer routinely measured.

Elevated levels of free catecholamines and metanephrines can also be detected in plasma. In children, the best sensitivity and specificity are obtained by measuring plasma normetanephrine using gender-specific pediatric reference ranges, with plasma normetanephrine being next best. Plasma metanephrine and epinephrine are not reliably elevated in children. Additionally, the patient should be instructed to abstain from caffeinated drinks, and to avoid acetaminophen, which can interfere with plasma normetanephrine assays. If possible, the blood sample should be obtained from an indwelling intravenous catheter, to avoid acute stress associated with venipuncture.

Most tumors in the area of the adrenal gland are readily localized by CT or MRI (Fig. 580-1), but extraadrenal tumors may be difficult to detect. 123I-metaiodobenzylguanidine is taken up by chromaffin tissue anywhere in the body and is useful for localizing small tumors. Venous catheterization with sampling of blood at different levels for catecholamine determinations is now only rarely necessary for localizing the tumor.

**DIFFERENTIAL DIAGNOSIS**

Various causes of hypertension in children must be considered, such as renal or renovascular disease; coarctation of the aorta; hyperthyroidism; Cushing syndrome; deficiencies of 11β-hydroxylase, 17α-hydroxylase, or 11β-hydroxysteroid dehydrogenase (type 2 isozyme); primary aldosteronism; adrenocortical tumors; and, rarely, essential hypertension (see Chapter 445). A nonfunctioning kidney may result...
from compression of a ureter or of a renal artery by a pheochromocytoma. Paroxysmal hypertension may be associated with porphyria or familial dysautonomia. Cerebral disorders, diabetes insipidus, diabetes mellitus, and hyperthyroidism must also be considered in the differential diagnosis. Hypertension in patients with neurofibromatosis may be caused by renal vascular involvement or by concurrent pheochromocytoma.

Neuroblastoma, ganglioneuroblastoma, and ganglioneuroma frequently produce catecholamines, but urinary levels of most catecholamines are higher in patients with pheochromocytoma, although levels of dopamine and homovanillic acid are usually higher in neuroblastoma. Secreting neurogenic tumors often produce hypertension, excessive sweating, flushing, pallor, rash, polyuria, and polydipsia. Chronic diarrhea may be associated with these tumors, particularly with ganglioneuroma, and at times may be sufficiently persistent to suggest celiac disease.

**TREATMENT**

These tumors must be removed surgically, but careful preoperative, intraoperative, and postoperative management is essential. Preoperative α- and β-adrenergic blockade and fluid loading are required. Because these tumors are often multiple in children, a thorough transabdominal exploration of all the usual sites offers the best opportunity to find them all. Appropriate choice of anesthesia and expansion of blood volume with appropriate fluids during surgery are critical to avoid a precipitous drop in blood pressure during operation or within 48 hr postoperatively. Manipulation and excision of these tumors result in marked increases in catecholamine secretion that increase blood pressure and heart rate. Surveillance must continue postoperatively.

Although these tumors often appear malignant histologically, the only accurate indicators of malignancy are the presence of metastatic disease or local invasiveness that precludes complete resection, or both. Approximately 10% of all adrenal pheochromocytomas are malignant. Such tumors are rare in childhood; pediatric malignant pheochromocytomas occur more frequently in extraadrenal sites and are often associated with mutations in the SDHB gene encoding a subunit of succinate dehydrogenase. Prolonged follow-up is indicated because functioning tumors at other sites may be manifested many years after the initial operation. Examination of relatives of affected patients may reveal other individuals harboring unsuspected tumors that may be asymptomatic.

Chapter 580  Pheochromocytoma

Bibliography
Adrenal masses are discovered with increasing frequency in patients undergoing abdominal imaging for reasons unrelated to the adrenal gland. The rate of detection of single adrenal masses has ranged from less than 1% to more than 4% of abdominal CT examinations in adults. The unexpected discovery of such a mass presents the clinician with a dilemma in terms of diagnostic steps to undertake and treatment interventions to recommend. The differential diagnosis of adrenal incidentaloma includes benign lesions such as cysts, hemorrhagic cysts, hematomas, and myelolipomas. These lesions can usually be identified on CT or MRI. If the nature of the lesion is not readily apparent, additional evaluation is required. Included in the differential diagnosis of lesions requiring additional evaluation are benign adenomas, pheochromocytomas, adrenocortical carcinoma, and metastasis from an extraadrenal primary carcinoma. Benign, hormonally inactive adrenocortical adenomas make up the majority of incidentalomas. Careful history, physical examination, and endocrine evaluation must be performed to seek evidence of autonomous cortisol, androgen, mineralocorticoid, or catecholamine secretion. Functional tumors require removal. If the adrenal mass is nonfunctional and larger than 4-6 cm, recommendations are to proceed with surgical resection of the mass. Lesions of 3 cm or less should be followed clinically with periodic reimaging. Treatment must be individualized; nonsecreting adrenal incidentalomas may enlarge and become hyperfunctioning. Nuclear scan, and occasionally fine-needle aspiration, may be helpful in defining the mass.

581.2 Adrenal Calcification

Calcification within the adrenal glands may occur in a wide variety of situations, some serious and others of no obvious consequence. Adrenal calcifications are often detected as incidental findings in radiographic studies of the abdomen in infants and children. The physician may elicit a history of anoxia or trauma at birth. Hemorrhage into the adrenal gland at or immediately after birth is probably the most common factor that leads to subsequent calcification (see Fig. 575-1 in Chapter 575). Although it is advisable to assess the adrenocortical reserve of such patients, there is rarely any functional disorder.

Neuroblastomas, ganglioneuromas, cortical carcinomas, pheochromocytomas, and cysts of the adrenal gland may be responsible for calcifications, particularly if hemorrhage has occurred within the tumor. Calcification in such lesions is almost always unilateral.

In the past, tuberculosis was a common cause both of calcification within the adrenals and of Addison disease. Calcifications may also develop in the adrenal glands of children who recover from the Waterhouse-Friderichsen syndrome; such patients are usually asymptomatic. Infants with Wolman disease, a rare lipid disorder caused by a deficiency of lysosomal acid lipase, have extensive bilateral calcifications of the adrenal glands (see Chapter 86.4).

GENETIC CONTROL OF EMBRYONIC GONADAL DIFFERENTIATION

Gonadal differentiation is a complex, multistep process that requires the sequential action and interaction of multiple gene products.
Early in the 1st trimester, the undifferentiated, bipotential fetal gonad begins as a thickening of the urogenital ridge, near the developing kidney and adrenal cortex. At 6 wk of gestation, the gonad contains germ cells, stromal cells that will become Leydig cells in testes, or theca, interstitial, or hilar cells in the ovary; and supporting cells that will develop into Sertoli cells in testes or granulosa cells in ovaries. In males, SRY (sex-determining region on the Y chromosome) is transiently expressed, followed by a sequential upregulation of a number of testis-specific genes. SRY may also suppress a putative factor that functions as repressor of male development. In the absence of SRY, the bipotential gonad will be able to develop into an ovary. Ovarian development is also characterized by expression of ovary-specific genes during the same time period. One such gene is R-spondin1. During the gestation time period of 6-9 wk, a number of genes are upregulated to the same degree in both the testis and the ovary, including WNT4 and CTNNB1.

A chromosome complement of 46,XX is necessary for the development of normal ovaries. Both the long and short arms of the X chromosome contain genes for normal ovarian development. The DSS (dosage sensitive/sex reversal) locus associated with the DAX1 (DSS adrenal hypoplasia on the X chromosome) gene, which is defective in patients with X-linked congenital adrenal hypoplasia and hypogonadotropic hypogonadism, is a member of the nuclear receptor superfamily and acts as a repressor of male gene expression. DAX1 acts by binding to a related nuclear receptor SF-1 (steroidogenic factor-1). In vitro, the signaling gene WNT4 stimulates expression of DAX1, resulting in the suppression of androgen synthesis in XX females. The WNTs are ligands that activate receptor-mediated signal transduction pathways and are involved in modulating gene expression as well as cell behavior, adhesion, and polarity. A key to its role in humans was elucidated by loss-of-function mutation of the WNT4 gene that was found in an 18 yr old 46,XX woman. She had absence of Müllerian-derived structures (uterus and fallopian tubes), unilateral renal agenesis, and clinical signs of androgen excess.

Mutations of the Wilms tumor 1 (WT1) gene, including alternative splicing, may also impact sex differentiation. WT1 mutations are associated with the Denys-Drash syndrome (early-onset renal failure with abnormal external genitalia and Wilms tumor). Haploinsufficiency of a 3-amino-acid (KTS) form of WT1 has been implicated in the gonadal dysgenesis of patients with Fraser syndrome (late-onset progressive glomerulopathy and 46,XY gonadal dysgenesis). Mutations in the FOXL2 and SF-1 genes are associated with ovarian failure. Mutation of the R-spondin1 gene has been described in individuals with 46,XX DSD (disorder of sex development). Other autosomal genes also play a role in normal ovarian organogenesis and testicular development. Several conditions of gonadal dysgenesis are associated with gross abnormalities of both autosomes and sex chromosomes. A deletion affecting the short arm of the X chromosome produces the typical somatic anomalies of Turner syndrome.

Development of the testis requires the short arm of the Y chromosome; this contains the testis-determining factor SRY gene. During male meiosis, the Y chromosome must segregate from the X chromosome so that both X and Y chromosomes do not occur in the same spermatogonia. The major portion of the Y chromosome is composed of Y-specific sequences that do not pair with the X chromosome. However, a minor portion of the Y chromosome shares sequences with the X chromosome and pairing does occur in this region. The genes and sequences in this area recombine between the sex chromosomes, behaving like autosomal genes. Therefore, the term pseudoautosomal region is used to describe this portion of the chromosome, and the term indicates genetic behavior of these genes relative to pairing and recombination events. The SRY gene is localized to the 35-kb portion proximal to the pseudoautosomal region of the Y chromosome. It contains a high-mobility group (HMG) nonhistone protein (HMG box), supporting SRY’s role as a transcriptional regulator of other genes involved in sex differentiation. The gonadal ridge forms at around 33 days of gestation. SRY is detected at 41 days, peaks at 44 days when testis cords are first visible, and persists into adulthood.

Other genes that are found on autosomes are important in this process. SOX9, a SRY-related gene containing a region homologous with the HMG box 9 of SRY, is located on chromosome 17. Mutations of this gene result in XY sex reversal and campomelic dysplasia. SF-1 on chromosome 9q33 is important in adrenal and gonadal development, as well as the development of gonadotropin-releasing hormone–secreting neurons in the hypothalamus. WT1, especially the KST isoform on chromosome 11p13, is needed for early gonadal, adrenal, and renal development. Fibroblast growth factor-9, GATA-4, XH-2, and SOX9 are also important.

When genetic recombination events on sex chromosomes extend beyond the pseudoautosomal region, X- and Y-specific DNA may be transferred between the chromosomes. Such aberrant recombinations result in X chromosomes carrying SRY, resulting in XX males, or Y chromosomes that have lost SRY, resulting in XY females. SRY acts as a transcriptional regulator to increase cellular proliferation, attract interstitial cells from adjacent mesonephros into the genital ridge, and stimulate testicular Sertoli cell differentiation. Sertoli cells act as an organizer of steroidogenic and germ cell lines and produce antimüllerian hormone (AMH) that causes the female duct system to regress. A Table 582-1 lists additional genes involved in sex development.

Development of the ovary was once thought to be a passive process in the absence of SRY. Although the morphologic changes in the developing ovary are less marked than in the testes, there are a number of sequentially expressed genes and pathways that are required for complete ovarian development as well as maintenance of ovarian integrity postnatally. One of these genes is R-spondin1, which if mutated can result in testicular or ovotesticular development in 46,XX individuals. Some peptides in the Wnt-signaling pathway may antagonize testicular development. This effect may be mediated by β-catenin signaling, which is required for suppressing testicular features. Once developed, the ovary requires FAX12 to preserve its differentiation and stability.

FUNCTION OF THE TESTES

Levels of placental chorionic gonadotropin peak at 8-12 wk of gestation and stimulate the fetal Leydig cells to secrete testosterone, the main hormonal product of the testis. In the classical androgen biosynthetic pathway, testosterone is then converted by the enzyme 5α-reductase to its more potent metabolite, dihydrotestosterone. This early period is critical for normal and complete virilization of the XY fetus. Defects in this process lead to different forms of atypical male development (see Chapter 588.2). After virilization occurs, fetal levels of testosterone decrease but are maintained at lower levels in the latter half of pregnancy by luteinizing hormone (LH) secreted by the fetal pituitary; this LH-mediated testosterone secretion is required for continued penile growth, and to some degree also for testicular descent.

As part of the normal transition from intrauterine to extrauterine life, perhaps related to the sudden withdrawal of maternal and placental hormones, newborns and young infants experience a transient surge of gonadotropins and sex steroids. This is the so-called minipuberty.

In males, LH and testosterone peak at 1-2 mo of age and then decline to reach prepubertal levels by 4-6 mo of age. Follicle-stimulating hormone (FSH), along with inhibin B, peak at 3 mo and decline to prepubertal levels by 9 and 15 mo, respectively. The LH rise is more dominant than that of FSH.

The neonatal surge may be important for postnatal maturation of the gonads, stabilization of male external genitalia, and perhaps also for gender identity and sexual behaviors. The postnatal surge in LH and testosterone is absent or blunted in infants with hypopituitarism, cryptorchidism, and complete androgen insensitivity syndrome. The development of nocturnal pulsatile secretion of LH marks the advent of puberty.

Within specific target cells, 6-8% of testosterone is converted by 5α-reductase to dihydrotestosterone, a more potent androgen (Fig. 582-1), and approximately 0.3% is acted on by aromatase to produce estradiol. Approximately half of circulating testosterone is bound to sex hormone–binding globulin and half to albumin; only 2% circulates in the free form. Plasma levels of sex hormone–binding globulin are low at birth, rise rapidly during the 1st 10 days of life, and then remain stable until the onset of puberty. Thyroid hormone may play a role in this...

Chromosomal rearrangements likely to include key genes are included.

↑, Increased; ACTH, adrenocorticotropin; AD, autosomal dominant (often de novo mutation); AMH, antimüllerian hormone; AR, autosomal recessive; CAH, congenital adrenal hyperplasia; DAX1, dosage sensitive/sex reversal adrenal hypoplasia on the X chromosome; DHEA, dehydroepiandrosterone; DHT, dehydrotestosterone; DSD, disorder of sex development; ND, not determined; PMDS, persistent müllerian duct syndrome; SF-1, steroidogenic factor-1; SRY, sex-determining region on the Y chromosome; StAR, steroidogenic acute regulatory; TF, transcription factor; WAGR, Wilms, aniridia, genital anomalies, and retardation; WTI, Wilms tumor 1; X, X-chromosomal; Y, Y-chromosomal.

**Figure 582-1** Biosynthesis of sex steroids. Dashed lines indicate enzymatic defects associated with 46,XY disorder of sex differentiation. 3β-HSD2, 3β-hydroxysteroid dehydrogenase type 2; AKR1C2/RoDH (Ox), one of the enzymes in the recently described alternative androgen biosynthetic pathway; ARO, aromatase; CYP17A1, the enzyme that catalyzes both 17α-hydroxylase (17-OH) and 17,20-lyase activities; HSD17B3, enzyme that catalyzes the 17-ketoreductase reaction; POR, P450 oxidoreductase; StAR, steroidogenic acute regulatory protein.

Physiologic increase because neonates with athyreosis (absence of the thyroid gland) have very low levels of sex hormone–binding globulin. AMH, a homodimeric glycoprotein hormone encoded by a gene on chromosome 19, is the earliest secreted product of the Sertoli cells of the fetal testis. Produced as a prohormone, its carboxyterminal fragment is cleaved to make it active. AMH transcription is initiated by SOX9 acting through the HMG box, while its expression is upregulated by SF-1 binding to its promoter and further interacting with SOX9, WT1, and GATA4. AMH binds to 2 distinct serine/threonine receptors, each having a single transmembrane domain. The activated type 1 receptor signals to the SMAD family of intracellular mediators.
The gene for the AMH receptor (on chromosome 12) is expressed in Sertoli cells. In the female, it is expressed in fetal müllerian duct cells and in fetal and postnatal granulosa cells. During sex differentiation in males, AMH causes involution of the müllerian ducts, which are embryologic precursors of the cervix and uterus. It works in concert with SF-1 to cause involution of the fallopian tubes.

AMH is secreted in males by Sertoli cells during both fetal and postnatal life. In females, it is secreted by granulosa cells from 36 wk of gestation to menopause but at lower levels. The serum concentration of AMH in males is highest at birth, whereas in females it is highest at puberty. After puberty, both sexes have similar serum concentrations of AMH. Its role in postnatal life is not yet fully characterized.

**Inhibin** is another glycoprotein hormone secreted by the Sertoli cells of the testes and granulosa and theca cells of the ovary. Inhibin A consists of an α-subunit disulfide linked to the β-A subunit, whereas inhibin B consists of the same α subunit linked to the β-B subunit. Activins are dimers of the B subunits, either homodimers (BA/BA, BB/BB) or heterodimers (BA/BB). Inhibins selectively inhibit whereas activins stimulate pituitary FSH secretion. By means of immunoenasays specific for inhibin A or B, it has been shown that inhibin A is absent in males and is present mostly in the luteal phase in women. Inhibin B is the principal form of inhibin in males and in females during the follicular phase. Inhibin B may be used as a marker of Sertoli cell function in males. FSH stimulates inhibit B secretion in females and males, but only in males is there also evidence for gonadotropin-independent regulation. Levels of inhibin B are currently being studied in children with various forms of gonadal and pubertal disorders. In males with delayed puberty, inhibin B may be a useful screening test to differentiate between constitutional delay of puberty and hypogonadotropic hypogonadism. In hypogonadotropic hypogonadism, the serum inhibin B level is very low to undetectable.

Like inhibin and activin, follistatin (a single-chain glycosylated protein) is produced by gonads and other tissues such as the hypothalamus, kidney, adrenal gland, and placenta. Follistatin inhibits FSH secretion principally by binding activins, thereby blocking the effects of activins at the level of both ovary and pituitary.

Many additional peptides act as mediators of the development and function of the testis. They include neurohormones such as growth hormone–releasing hormone, gonadotropin-releasing hormone, corticotropin-releasing hormone, oxytocin, arginine vaspessin, somatostatin, substance P, and neuropeptide Y; growth factors such as insulin-like growth factors and insulin-like growth factor–binding proteins, TGF-β, and fibroblast, platelet-derived, and nerve growth factors; vasoactive peptides; and immune-derived cytokines such as tumor necrosis factor and interleukins 1, 2, 4, and 6.

Clinical patterns of pubertal changes vary widely (see Chapters 14 and 561 covering pubertal maturation). In 95% of boys, enlargement of the genitals begins between 9.5 and 13.5 yr of age, reaching maturity at 13-17 yr of age. In a minority of normal boys, puberty begins after 15 yr of age. In some boys, pubertal development is completed in less than 2 yr, but in others it may take longer than 4.5 yr. Pubertal development and the adolescent growth spurt occur at an older age in boys than in girls.

The median age of sperm production (spermarche) is 14 yr. This event occurs in midpuberty as judged by pubic hair, testis size, evidence of growth spurt, and testosterone levels. Nighttime levels of FSH are in the adult male range at the time of spermarche; the first conscious ejaculation occurs at about the same time.

**FUNCTION OF THE OVARIES**

In the normal female, the undifferentiated gonad can be identified histologically as an ovary by 10-11 wk of gestation, after the upregulation of R-spondin1. Oocytes are present from the 4th mo of gestation and reach a peak of 7 million by 5 mo of gestation. For normal maintenance, oocytes need granulosa cells to form primordial follicles. Functional FSH (but not LH) receptors are present in oocytes of primary follicles during follicular development. Normal X chromosomes are needed for maintenance of oocytes. In contrast to somatic cells, in which only 1 X chromosome is active, both Xs are active in germ cells. At birth, the ovaries contain approximately 1 million active follicles, which decrease to 0.5 million by menarche. Thereafter, they decrease at a rate of 1,000/mo, and at an even higher rate after the age of 35 yr.

The hormones of the fetal ovary are provided in most part by the fetoplacental unit. As in males, peak gonadotropin secretion occurs in fetal life and then again at 2-3 mo of life, with the lowest levels at about 6 yr of age. By contrast to males, the FSH surge predominates over LH in females. FSH peaks around 3-6 mo of age, declines by 12 mo, but remains detectable for 24 mo. Under LH influence, estradiol peaks at 2-6 mo of age. The inhibin B response is variable, peaking between 2 and 12 mo and remaining above prepubertal levels until 24 mo. In both infancy and childhood, gonadotropin levels are higher in females than in males.

The most important estrogens produced by the ovary are estradiol-17β (E2) and estrone (E1); estriol is a metabolic product of these, and all 3 estrogens may be found in the urine of mature females. Estrogens also arise from androgens produced by the adrenal gland and both the female and male gonads (see Fig. 574-1 in Chapter 574). This conversion explains why in certain types of disorders of sex differentiation in males, feminization occurs at puberty. In 17-koesteroid reductase deficiency, for example, the enzymatic block results in markedly increased secretion of androstenedione, which is converted in the peripheral tissues to estradiol and estrone. These estrogens, in addition to those directly secreted by the testis, result in gynecomastia. Estradiol produced from testosterone in the complete androgen insensitivity syndrome causes complete feminization in XY individuals.

Estradiol regulates a host of functionally different activities in multiple tissues. There are at least 2 distinct estrogen receptors with different expression patterns. The ovary also synthesizes progestrone, the main progesterational steroid; the adrenal cortex and testis also synthesize progesterone where it is a precursor for other adrenal and testicular hormones.

A host of other hormones with autocrine, paracrine, and intracrine effects have been identified in the ovary. They include inhibins, activins, relaxin, and growth factors insulin-like growth factor-1, TGF-α and TGF-β, and cytokines.

Plasma levels of estradiol increase slowly but steadily with advancing sexual maturation and correlate well with clinical evaluation of pubertal development, skeletal age, and rising levels of FSH. Levels of LH do not rise until secondary sexual characteristics are well developed. Estrogens, like androgens, inhibit secretion of both LH and FSH (negative feedback). In females, estrogens also provoke the surge of LH secretion that occurs in the mid–menstrual cycle. The capacity for this positive feedback is another maturational milestone of puberty.

The average age at menarche in American girls is approximately 12.5-13 yr; but the range of “normal” is wide, and 1-2% of normal girls have not menstruated by age 15 yr. The age at onset of pubertal signs varies, with recent studies suggesting earlier ages than previously thought, especially in the U.S. African-American population (see Chapter 561). Menarche generally correlates closely with skeletal age. Maturation and closure of the epiphyses is at least partially estrogen dependent, as demonstrated by a very tall 28 yr old, normally masculinized male with continued growth as a result of incomplete closure of the epiphyses, who proved to have complete estrogen insensitivity caused by an estrogen-receptor defect.

**DIAGNOSTIC TESTING**

Improved, sensitive, and specific assays for pituitary and gonadal hormones that can be measured in small amounts of blood have contributed to rapid advances in the understanding of normal and abnormal hypothalamic-pituitary-gonadal interactions. In male infants, measurements of LH, FSH, and testosterone can detect pituitary and testicular defects. Leydig cell integrity in childhood can be determined by the testosterone response following human chorionic gonadotropin administration. (One protocol is to use 5,000 IU IM daily for 3 days; other protocols are available.) The integrity, as well as the maturity, of the hypothalamic-pituitary-gonadal axis in males and females can be assessed by measuring serial sex steroid, LH, and FSH levels after the subcutaneous administration of the gonadotropin-releasing hormone analog leuprolide. An ultrasensitive LH assay has been shown to
differentiate between boys with delayed puberty and those with complete, but not partial, hypogonadotropic hypogonadism.

The normal range for inhibin B levels has been established in infant boys. Inhibin B may be a marker of spermatogenesis and also of tumors such as granulosa cell tumors. Inhibin may be involved in tumor suppression. Estrogen-receptor assays may be clinically useful in the management of various ovarian cancers. AMH measurements are useful in the evaluation of children with nonpalpable gonads and disorders of sex development.

**THERAPEUTIC USE OF SEX STEROIDS**

The estrogenic effects of polyhalogenated aromatic hydrocarbons may in part be a result of inhibition of estradiol sulfation by estrogen sulfotransferase, an important pathway of estradiol inactivation. Naturally occurring estrogens administered orally are rapidly destroyed by gastrointestinal and liver enzymes; accordingly, they are usually given as conjugates or esters. The most widely used oral preparations are equine conjugated estrogens (Premarin) and ethinyl estradiol. Estrogen-containing skin patches for transdermal absorption are also used. With improvements in the understanding of estrogen and estrogen-receptor interactions, a new class of compounds called selective estrogen-receptor modulators has been synthesized. For example, raloxifene, a nonsteroidal benzothiophene derivative, acts as an estrogen agonist in bone and liver and as an estrogen antagonist in breast and uterus.

Androgens, such as testosterone, are generally injected intramuscularly as long-acting esters (enanthate or cypionate, most commonly) because of their potency and steady response. Transdermal testosterone patches and a cutaneously applied gel have to date been used mostly in adults with hypogonadism because of the difficulty in titrating the doses needed during childhood and adolescence. Oral preparations, such as methyltestosterone or fluoxymesterone, do not produce so potent an androgenic response and may be hepatotoxic. Testosterone undecenoate, another oral preparation, is used in Europe but not in the United States. Sublingual (microspheres or pellets) and buccal (absorption via the buccal mucosa) preparations of testosterone are in development.

Chapter 583

Hypofunction of the Testes
Omar Ali and Patricia A. Donohoue

Testicular hypofunction during fetal life can be a component of some types of disorders of sex development (see Chapter 588.2) and may lead to varying degrees of ambiguous genitalia. After birth, neonates undergo “minipuberty” with relatively high levels of gonadotropins and sex steroids, but this phenomenon is transient and its absence does not lead to any obvious clinical findings. Because prepubertal children normally do not produce significant amounts of testosterone and are not yet producing sperm, there are no discernible effects of testicular hypofunction in this age group. Testicular hypofunction from the age of puberty onward may lead to testosterone deficiency, infertility, or both. Such hypofunction may be primary in the testes (primary hypogonadism) or secondary to deficiency of pituitary gonadotropic hormones (secondary hypogonadism). Both types may be caused by inherited genetic defects or acquired causes, and in some cases the etiology may be unclear, but the level of the lesion (primary or secondary) is usually well defined; patients with primary hypogonadism have elevated levels of gonadotropins (hypergonadotropic); those with secondary hypogonadism have inappropriately low or absent levels (hypogonadotropic). Table 583-1 details the etiologic classification of male hypogonadism.

### 583.1 Hypergonadotropic Hypogonadism in the Male (Primary Hypogonadism)

**Omar Ali and Patricia A. Donohoue**

**ETIOLOGY**

Some degree of testicular function is essential in the development of phenotypically male newborns. If testicular function is present, sex differentiation is normally complete by the 14th wk of intrauterine life. Hypogonadism may occur after phenotypically male genitalia have developed for a variety of reasons; genetic or chromosomal anomalies may lead to testicular hypofunction that does not become apparent until the time of puberty, when these boys may have delayed or incomplete pubertal development. In other cases, normally developed testes may be damaged by infarction, trauma, radiation, chemotherapy, infections, infiltration, or other causes after sexual differentiation has occurred. In some cases, genetic defects may predispose to atrophy or maldescent; or torsion or infarction or may lead to progressive testicular damage and atrophy after a period of normal development. If testicular compromise is global, both testosterone secretion and fertility

</table>
(sperm production) are likely to be affected. Even when the primary defect is in testosterone production, low levels of intratesticular testosterone will frequently lead to infertility. The reverse is not necessarily true. Defects in sperm production and in the storage and transit of sperm may not be associated with low testosterone levels; infertility may thus be seen in patients with normal testosterone levels, normal libido, and normal secondary sexual characteristics.

Various degrees of primary hypogonadism also occur in a significant percentage of patients with chromosomal aberrations as in Klinefelter syndrome, males with more than one X chromosome, and XX males. These chromosomal anomalies are associated with other characteristic findings. Noonan syndrome is associated with cryptorchidism and infertility, but other (nongonadal) features dominate its clinical picture.

**Congenital Anorchia or Testicular Regression Syndrome**

Boys in whom the external genitalia have developed normally (or nearly normally) and müllerian duct derivatives (uterus, fallopian tubes) are absent have obviously had testicular function for at least some part of gestation. If their testes cannot be palpated at birth, they are said to have cryptorchidism. In most such cases, the testes are undescended or retractile, but in some cases no testes are found in any location, even after extensive investigation. This syndrome of absence of testes in a phenotypic male with normal 46,XY karyotype (indicating that there was some period of testicular function in intrauterine life) is known as “vanishing testes,” “congenital anorchia,” or “testicular regression syndrome.”

Testicular regression syndrome is not uncommon. Cryptorchidism occurs in 1.5–9% of male births and in 10–20% of these cases, the testes are impalpable. Of children with impalpable testes, up to 50% may have no detectable testes after extensive investigation. Most cases appear to be sporadic and are thought to be a result of torsion or vascular accidents. The incompletely descended testis may be more prone to torsion and this may be one of the causes of “vanishing testes.” Most cases are sporadic but in a subset of patients testicular regression syndrome occurs in monozygotic twins or in families with other affected individuals, suggesting a genetic etiology. Some cases are associated with microopenis and in these cases the testicular loss probably occurred after the 14th wk, but well before the time of birth, or this may indicate a preexisting dysfunction of male hormonal development. Low levels of testosterone (<10 ng/dL) and markedly elevated levels of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) are found in the early postnatal months; thereafter, levels of gonadotropins tend to decrease even in agonal children, rising to very high levels again as the pubertal years approach. Stimulation with human chorionic gonadotropin (hCG) fails to evoke an increase in the level of testosterone. Serum levels of antimullerian hormone (AMH) are undetectable or low. All patients with undetectable testes should be tested for AMH and should undergo an hCG stimulation test. If the results indicate that no testicular tissue is present (absent AMH and no rise in testosterone after hCG stimulation), then the diagnosis of testicular regression syndrome is confirmed. If testosterone secretion is demonstrated, then imaging with abdominal MRI and/or surgical exploration is indicated. A small fibrotic nodule may be found at the end of the spermatic cord in many cases of testicular regression syndrome. Treatment of male hypogonadism (primary or secondary) is discussed in Chapter 583.2. There is no possibility of normal fertility in these patients.

**Chemotherapy and Radiation-Induced Hypogonadism**

Testicular damage is a frequent consequence of chemotherapy and radiotherapy for cancer. The frequency and extent of damage depend on the agent used, total dose, duration of therapy, and posttherapy interval of observation. Another important variable is age at therapy; germ cells are less vulnerable in prepubertal than in pubertal and postpubertal boys. Chemotherapy is most damaging if more than 1 agent is used. The use of alkylating agents such as cyclophosphamide in prepubertal children does not impair pubertal development, even though there may be biopsy evidence of germ cell damage. High doses of cyclophosphamide and ifosfamide are associated with infertility. Cisplatin causes transient azoospermia or oligospermia at lower doses, while higher doses (400–600 mg/m²) can cause permanent infertility. Interleukin 2 can depress Leydig cell function, whereas interferon-α does not seem to affect gonadal function. Most chemotherapeutic agents produce azoospermia and infertility; Leydig cell damage (leading to low testosterone levels) is less common. In many cases, the damage is transient and sperm counts recover after 12–24 mo. Both chemotherapy and radiotherapy are associated with an increase in the percentage of abnormal gametes, but data concerning the outcomes of pregnancies after such therapy have not shown any increase in genetically mediated birth defects, possibly because of selection bias against abnormal sperm.

**Radiation damage** is dose dependent. Temporary oligospermia can be seen with doses as low as 0.1 Gy, with permanent azoospermia seen with doses greater than 2 Gy. Recovery of spermatogenesis can be seen as long as 5 yr (or more) after irradiation, with higher doses leading to slower recovery. Leydig cells are more resistant to irradiation. Mild damage as determined by elevated LH levels can be seen with up to 6 Gy; doses greater than 30 Gy cause hypogonadism in most patients. Whenever possible, testes should be shielded from irradiation. Testicular function should be carefully evaluated in adolescents after multimodal treatment for cancer in childhood. Replacement therapy with testosterone and counseling concerning fertility may be indicated. The storage of sperm prior to chemotherapy or radiation treatment in postpubertal males is an option. Even in those cases where sperm counts are abnormal, recovery is possible, though the chances of recovery decline with increasing dose of radiation. If sperm counts remain low, fertility is still possible in some cases with testicular sperm extraction and intracytoplasmic sperm injection.

**Sertoli Cell–Only Syndrome**

Small testes and azoospermia are seen in patients with the extremely rare Sertoli cell–only syndrome (germ cell aplasia, or Del Castillo syndrome). These patients have no germ cells in the testes, but usually have normal testosterone production, and present as adults with the complaint of infertility. Most cases are sporadic and idiopathic, but deletions involving the azoospermia factor (AZF) region of the Y chromosome (Yq11) may be found in some cases.

**Other Causes of Testicular Hypofunction**

Atrophy of the testes may follow damage to the vascular supply as a result of manipulation of the testes during surgical procedures for correction of cryptorchidism or as a result of bilateral torsion of the testes. **Acute orchitis** is common in pubertal or adult males with mumps and may lead to subfertility in 13% of cases, though infertility is rare. Testosterone secretion usually remains normal. The incidence of mumps orchitis in postpubertal males has increased in some areas as a result of decrease in measles, mumps, and rubella vaccination uptake. Autoimmune polyendocrinopathy may be associated with primary hypogonadism (associated with anti-P450scx antibodies) but this appears to be more common in females.

**Testicular Dysgenesis Syndrome**

The incidence of testicular cancer has increased in many developed societies while the incidence of cryptorchidism, hypospadias, low sperm counts, and sperm abnormalities also appears to have increased in some, but not all, studies. It has been proposed that all these trends are linked by prenatal testicular dysgenesis. The hypothesis is that some degree of testicular dysgenesis develops in intrauterine life from genetic as well as environmental factors, and is associated with increased risk of cryptorchidism, hypospadias, hypofertility, and testicular cancer. The environmental influences that have been implicated in this syndrome include environmental chemicals that act as endocrine disruptors, such as bisphenol A and phthalates (components of many types of plastics), several pesticides, phytoestrogens or mycoestrogens, and other chemicals. The fact that these lesions can be reproduced in some animal models by environmental chemicals has led to efforts to remove...
these chemicals from products used by infants and pregnant mothers, and from the environment in general. Nonetheless, the evidence is only suggestive and is not conclusive.

**CLINICAL MANIFESTATIONS**

Primary hypogonadism may be suspected at birth if the testes and penis are abnormally small. Normative data are available for different populations. The condition often is not noticed until puberty, when secondary sex characteristics fail to develop. Facial, pubic, and axillary hair is scant or absent; there is neither acne nor regression of scalp hair; and the voice remains high pitched. The penis and scrotum remain infantile and may be almost obscured by pubic fat; the testes are small or not palpable. Fat accumulates in the region of the hips and buttocks and sometimes in the breasts and on the abdomen. The epiphyses close later than normal; therefore, extremities are long. The span may be several inches longer than the height, and the distance from the symphysis pubis to the soles of the feet (lower segment) is much greater than that from the symphysis to the vertex (upper segment). The proportions of the body are described as eunuchoid. The upper to lower segment ratio is considerably less than 0.9. Many individuals with milder degrees of hypogonadism may be detected only by appropriate studies of the pituitary-gonadal axis. Examination of the testes should be performed routinely by pediatricians; testicular volumes as determined by comparison with standard orchidometers or by measurement of linear dimensions should be recorded.

**DIAGNOSIS**

Levels of serum FSH and, to a lesser extent, of LH are elevated to greater than age-specific normal values in early infancy (when “mini-puberty” normally occurs and the gonadotropins are normally inhibited). This is followed by a period of time when even gonadal children may not exhibit significant elevation in gonadotropins, indicating that the gonadotropins are also suppressed at this stage by some mechanism independent of feedback inhibition by gonadal hormones. In the latter half of childhood and several years prior to the onset of puberty, this inhibition is released and gonadotropin levels again rise above age-matched normals in subjects with primary hypogonadism. These elevated levels indicate that even in the prepubertal child there is an active hypothalamic-gonadal feedback relationship. After the age of 11 yr, FSH and LH levels rise significantly, reaching the castratorange. Measurements of random plasma testosterone levels in prepubertal boys are not helpful because they are ordinarily low in normal prepubertal children, rising during puberty to attain adult levels. During puberty, these levels, when measured in an early-morning blood sample, correlate better with testicular size, stage of sexual maturity, and bone age than with chronological age. In patients with primary hyponadism, testosterone levels remain low at all ages. There is an attenuated rise or no rise at all after administration of hCG, in contrast to normal males in whom hCG produces a significant rise in plasma testosterone at any stage of development.

AMH is secreted by the Sertoli cells and this secretion is suppressed by testosterone. As a result, AMH levels are elevated in prepubertal boys and suppressed at onset of puberty. Boys with primary hypogonadism continue to have elevated AMH levels in puberty. Detection of AMH may be used in prepubertal years as an indicator of the presence of testicular tissue (e.g., in patients with bilateral cryptorchidism). Inhibin B is also secreted by the Sertoli cells, is present throughout childhood, and rises at onset of puberty (more in boys than in girls). It may be used as another marker of the presence of testicular tissue in bilateral cryptorchidism and as a marker of spermatogenesis (e.g., in delayed puberty, cancer survivors, and patients with Noonan syndrome). Bone age x-rays are useful to document delayed bone age in patients with constitutional growth delay as well as primary hypogonadism.

**NOONAN SYNDROME**

**Etiology**

The term Noonan syndrome has been applied to males and females with normal karyotypes who have certain phenotypic features that occur also in females with Turner syndrome (although the genetic causes are completely distinct) (see Chapter 81.4). Noonan syndrome occurs in 1 in 1,000-2,500 live births. Approximately 20% of the cases are familial and exhibit autosomal dominant inheritance. Males and females are equally affected. It is now thought that several mutations in the renin-angiotensin system (RAS)–mitogen-activated protein kinase (MAPK) pathway can cause Noonan syndrome and other related disorders and such mutations are currently detected in approximately 70% of the cases of Noonan syndrome. Missense mutations in PTPN11—a gene on chromosome 12q24.1 encoding the nonreceptor protein tyrosine phosphatase SHP-2—are seen in about half the cases. Mutations in other genes in this pathway, including SHOC2, CBL, SOS1, KRAS, NRAS, BRAF, and RAF1, as well as duplications of the 12q24 region, are also seen. Phenotypic features of Noonan syndrome therefore overlap with other syndromes involving the RAS-MAPK pathway, such as Leopard syndrome and cardiofaciocutaneous syndrome.

**Clinical Manifestations**

The most common abnormalities are short stature, webbing of the neck, pectus carinatum or pectus excavatum, cubitus valgus, right-sided congenital heart disease, and characteristic facies. Hypertelorism, epicanthus, downward-slanting palpebral fissures, ptosis, micrognathia, and ear abnormalities are common. Other abnormalities such as clinodactyly, hernias, and vertebral anomalies occur less frequently. As opposed to Turner syndrome, the mean IQ of school-age children with Noonan syndrome is subnormal at 86, with a range of 53-127. Verbal IQ tends to be better than performance IQ. High-frequency sensorineural hearing loss is common. The cardiac defect is most often pulmonary valvular stenosis, hypertrophic cardiomyopathy, or atrial septal defect. Hepatosplenomegaly and several hematologic diseases, including low clotting factors XI and XII, acute lymphoblastic leukemia, and chronic myelomonocytic leukemia, are noted. Noonan-like features can be part of the phenotypic variation of the NFI (neurofibromatosis) gene mutation, possibly as a result of common involvement of the RAS-MAPK pathway in both diseases. Males frequently have cryptorchidism and small testes. Testosterone secretion may be low or normal, but spermatogenesis may be affected even in those with normal testosterone (and normal secondary sexual characteristics). Serum inhibin-B is a useful marker of Sertoli cell function in these patients. Puberty is delayed and adult height is achieved by the end of the 2nd decade and usually reaches the lower limit of the normal population. Prenatal diagnosis should be suspected in fetuses with normal karyotype, edema, or hydrops and short femur length.

**Treatment**

Human growth hormone results in improvement in growth velocity in many Noonan syndrome patients, comparable to that seen in patients with Turner syndrome, and studies show a mean increase in height standard deviation score ranging from 1.3-1.7, corresponding to 9.5–13 cm for boys and 9.0–9.8 cm for girls. Many patients with Noonan syndrome reach normal height without growth hormone therapy, but treatment is recommended for those who fall below the 3rd percentile for height. The recommended dose is up to 66 µg/kg/day of recombinant growth hormone. Patients with Noonan syndrome and demonstrable PTPN11 mutations grow less well and are less responsive to growth hormone treatment than those without mutations. They have lower insulin-like growth factor-1 and higher growth hormone levels, suggesting partial growth hormone resistance because of post-receptor-signaling defects. Treatment of male hypogonadism is discussed in Chapter 583.2.

**KLINEFELTER SYNDROME**

See also Chapter 81.

**Etiology**

Klinefelter syndrome is the most common sex chromosome aneuploidy in males, with an incidence of 0.1–0.2% in the general population (1 in 500-1,000) and rising to 4% among infertile males and 10-11% in those with oligospermia or azoospermia. Approximately 80% of them have a 47,XXY chromosome complement, while mosaics
and higher degrees of polyX are seen in the remaining 20%. Even with as many as 4 X chromosomes, the Y chromosome determines a male phenotype. The chromosomal aberration most often results from meiotic nondisjunction of an X chromosome during parental gametogenesis; the extra X chromosome is maternal in origin in 54% and paternal in origin in 46% of patients. A national study in Denmark revealed a prenatal prevalence of 213 per 100,000 male fetuses, but in adult men the prevalence was only 40 per 100,000, suggesting that only 1 in 4 of adult males with Klinefelter syndrome was diagnosed.

Clinical Manifestations

In patients who do not have a prenatal diagnosis, the diagnosis is rarely made before puberty because of the paucity or subtleness of clinical manifestations in childhood. Behavioral or psychiatric disorders may be apparent long before defects in sexual development. These children tend to have learning disabilities and deficits in “executive function” (concept formation, problem solving, task switching, and planning), and the condition should be considered in boys with psychosocial, learning, or school adjustment problems. Affected children may be anxious, immature, or excessively shy and tend to have difficulty in social interactions throughout life. In a prospective study, a group of children with 47,XXXY karyotypes identified at birth exhibited relatively mild deviations from normal during the 1st 5 yr of life. None had major physical, intellectual, or emotional disabilities; some were inactive, with poorly organized motor function and mild delay in language acquisition. Problems often first become apparent after the child begins school. Full-scale IQ scores may be normal, with verbal IQ being somewhat decreased. Verbal cognitive deficits and underachievement in reading, spelling, and mathematics are common. By late adolescence, many boys with Klinefelter syndrome have generalized learning disabilities, most of which are language based. Despite these difficulties, most complete high school.

The patients tend to be tall, slim, and have a specific tendency to have long legs (disproportionate to the arms, and longer than those seen with other causes of hypogonadism), but body habitus can vary markedly. The testes tend to be small for age, but this sign may become apparent only after puberty, when normal testicular growth fails to occur. The phallus tends to be smaller than average, and cryptorchidism is more common than in the general population. Bone mineral density may be low in adults with Klinefelter syndrome and this correlates with lower testosterone levels.

Pubertal development may be delayed, although some children undergo apparently normal or nearly normal virilization. Despite normal testosterone levels, serum LH and FSH concentrations and their responses to gonadotropin-releasing hormone (GnRH) stimulation are elevated starting at around 13 yr of age. Approximately 80% of adults have gynecomastia; they have sparser facial hair, most shaving less often than daily. The most common testicular lesions are spermatogenetic arrest and Sertoli cell predominance. The sperm have a relatively low frequency of sperm head defects, including elongated radius, pseudoepiphyses, scoliosis or kyphosis, growth stops, gonadotropins become elevated, and testosterone levels are slightly low. Inhibin B levels are normal in early puberty, decrease in late puberty, and are low in adults with the syndrome. Elevated levels are associated with cognitive deficits.

Laboratory Findings

Most males with Klinefelter syndrome go through life undiagnosed. The chromosomes should be examined in all patients suspected of having Klinefelter syndrome, particularly those attending child guidance, psychiatric, and cognitive disability clinics. In infancy, inhibin B and AMH levels are normal but testosterone levels are lower than in controls. Before 10 yr of age, boys with 47,XXX Y Klinefelter syndrome have normal basal plasma levels of FSH and LH. Responses to gonadotropin-stimulating hormone and to hCG are normal. The testes show normal growth early in puberty, but by midpuberty the testicular growth stops, gonadotropins become elevated, and testosterone levels are slightly low. Inhibin B levels are normal in early puberty, decrease in late puberty, and are low in adults with the syndrome. Elevated levels of estradiol, resulting in a high estradiol to testosterone ratio, account for the development of gynecomastia during puberty. Sex hormone–binding globulin levels are elevated, further decreasing free testosterone levels. Long androgen receptor polyglutamine (CAG) repeat length is associated with the more-severe phenotype, including gynecomastia, small testes, and short penile length.

Testicular biopsy before puberty may reveal only deficiency or absence of germinal cells. After puberty, the seminiferous tubular membranes are hyalinized, and there is adenomatous clumping of Leydig cells. Sertoli cells predominate. Azospermatia is characteristic, and infertility is the rule.
Management

Boys known to have Klinefelter syndrome should be monitored closely for speech, learning, and behavioral problems, and referred for early evaluation and treatment as needed. Testosterone, LH, and FSH levels should be checked at 11-12 yr of age and replacement therapy with a testosterone preparation is recommended once FSH and LH begin to rise above normal. Fasting glucose, lipids, and hemoglobin A_c should also be obtained as these children are at risk for central adiposity and metabolic syndrome. A baseline dual-energy x-ray absorptiometry scan to assess bone density is also recommended by some authorities. Although testosterone treatment will normalize testosterone levels, stimulate the development of secondary sexual characteristics, increase bone mass and muscle mass, and improve body composition, it will not improve fertility (and will, in fact, suppress spermatogenesis). There is some evidence that it also improves mood and may have a positive effect on cognition and social functioning but the findings are not conclusive at this time. Either long-acting testosterone injections or daily application of testosterone gel may be used (testosterone patches have a high incidence of skin rash and are not frequently used in pediatrics). Testosterone enanthate or cypionate ester may be used in a starting dose of 25-50 mg injected intramuscularly every 3-4 wk, with 50-mg increments every 6-9 mo until a maintenance dose for adults (200-250 mg every 3-4 wk) is achieved. At that time, testosterone one patches or testosterone gel may be substituted for the injections. Depending on patient and physician preference, transdermal testosterone may also be used as initial treatment instead of injections. For older boys, larger initial doses and increments can achieve more rapid virilization. The various transdermal preparations differ somewhat from each other and standard references should be consulted for recommendations regarding dosage and mode of application.

Gynecomastia may be treated with aromatase inhibitors (which will also increase endogenous testosterone levels) but medical treatment is not always successful and plastic surgery may be needed. Fertility is usually not an issue in the pediatric age group, but adults can father children using testicular sperm extraction followed by intracytoplasmic sperm injection. Because sperm counts decrease rapidly after onset of puberty in children with Klinefelter syndrome, sperm banking during early puberty is an option that can be discussed with a fertility specialist. Sperm counts can be stimulated using hCG treatment prior to testicular sperm extraction. Therapy, counseling and psychiatric services should be provided as needed for learning difficulties and psychosocial disabilities.

XX MALES

This disorder is thought to occur in 1 in 20,000 newborn males. Affected individuals have a male phenotype, small testes, a small phallus, and no evidence of ovarian or müllerian duct tissue. They appear, therefore, to be distinct from the ovotesticular disorder of sexual development. Undescended testes and hypospadias occur in a minority of patients. Infertility occurs in practically all cases and the histologic features of the testes are essentially the same as in Klinefelter syndrome. Patients with the condition usually come to medical attention in adult life because of hypogonadism, gynecomastia, or infertility. Hypergonadotropic hypogonadism occurs secondary to testicular failure. A few cases have been diagnosed perinatally as a result of discrepancies between prenatal ultrasonography and karyotype findings.

In 90% of XX males with normal male external genitalia, 1 of the X chromosomes carries the SRY (sex-determining region on the Y chromosome) gene. The exchange from the Y to the X chromosome occurs during paternal meiosis, when the short arms of the Y and X chromosomes pair. XX males inherit 1 maternal X chromosome and 1 paternal X chromosome containing the translocated male-determining gene. A few cases of 46,XX males with 9P translocations have also been identified. Most XX males who are identified before puberty have hypospadias or microperineum; this group of patients may lack X-specific sequences, suggesting other mechanisms for virilization. Fluorescent in situ hybridization and primed in situ labeling have been used to identify small SRY DNA segments. Yp fragment abnormalities may result in sexually ambiguous phenotypes.

45,X MALES

In a few male patients recognized with a 45,X karyotype, Yp sequences are translocated to an autosomal chromosome. In 1 instance, the terminal short arm of the Y chromosome was translocated onto an X chromosome. In another, SRY/autosomal translocation was postulated. A male with 45,X karyotype and Leri-Weill dyschondrosteosis, SHOX gene loss, and SRY to Xp translocation also has been described.

47,XXX MALES

A Japanese male with poor pubic hair development, hypoplastic scrotal testes (4 mL), normal penis and normal height, gynecomastia, and severe cognitive impairment had 47,XXX karyotype caused by an abnormal X-Y interchange during paternal meiosis and X-X nondisjunction during maternal meiosis.

Bibliography is available at Expert Consult.

583.2 Hypogonadotropic Hypogonadism in the Male (Secondary Hypogonadism)

Omar Ali and Patricia A. Donohoe

In hypogonadotropic hypogonadism, lack of gonadal function is secondary to deficiency of 1 or both gonadotropins: FSH or LH. The primary defect may lie either in the anterior pituitary or in the hypothalamus. Hypothalamic etiologies result in deficiency of GnRH. The tests are normal but remain in the prepubertal state because stimulation by gonadotropins is lacking. The disorder may be recognized in infancy but is much more commonly recognized because of marked pubertal delay. Rarely, patients with an inherited form of hypogonadotropic hypogonadism (HH) may go through puberty and may present with hypogonadism as adults.

ETIOLOGY

HH may be genetic or acquired. Several different genes can cause inherited forms of HH; the affected genes may be upstream of GnRH, at the level of GnRH receptors, or at the level of gonadotropin production. In addition, various genetic defects in transcription factors such as POUF-1, LHX-3, LHX-4, and HESX-1 lead to defects in pituitary development and multiple pituitary hormone deficiencies, including deficiency of gonadotropins. Acquired pituitary gonadotropin deficiency may develop from various lesions in the hypothalamic-pituitary region (e.g., tumors, infiltrative disease, autoimmune disease, trauma, stroke).

Isolated Gonadotropin Deficiency

Isolated gonadotropin deficiency in which other pituitary hormone levels are normal is more likely to be from defects in the secretion of GnRH from the hypothalamus rather than defects in gonadotropin synthesis in the pituitary. It affects approximately 1 in 10,000 males and 1 in 50,000 females and encompasses a heterogeneous group of entities. Many cases are associated with anosmia and this combination of anosmia and HH defines Kallmann syndrome.

Kallmann syndrome is the most common form of HH and is genetically heterogeneous, with autosomal recessive, X-linked, and autosomal dominant forms of inheritance. Clinically, it is characterized by its association with anosmia or hyposmia; 85% of the cases are autosomal and 15% are X-linked. The X-linked form (KAL1) is caused by mutations of the KAL1 gene at Xp22.3. This leads to failure of olfactory axons and GnRH-expressing neurons to migrate from their common origin in the olfactory placode to the brain. The KAL1 gene product anosmin-1, an extracellular 95 kDa matrix glycoprotein, facilitates neuronal growth and migration. The KAL gene is also expressed in various parts of the brain, facial mesenchyme, and mesonephros and metanephros, thus explaining some of the associated findings in patients with Kallmann syndrome, such as synkinetasia (mirror movements), hearing loss, midfacial defects, and renal agenesis.

Some kindreds contain anosmic individuals with or without hypogonadism; others contain hypogonadal individuals who are anosmic.

Cleft lip and palate, hypotelorism, median facial clefts, sensorineural hearing loss, unilateral renal aplasia, neurologic deficits, and other findings occur in some affected patients. When Kallmann syndrome is caused by terminal or interstitial deletions of the Xp22.3 region, it may be associated with other contiguous gene syndromes, such as steroid sulfatase deficiency, chondrodysplasia punctata, X-linked ichthyosis, or ocular albinism.

The autosomal dominant form of Kallmann syndrome (KAL2) occurs in up to 10% of patients, and is caused by a loss of function mutation in the fibroblast growth factor receptor 1 (FGFR1) gene. Cleft lip and palate are associated with KAL2 but not with KAL1. Oligodontia and hearing loss may occur with both KAL1 and KAL2. A variety of other genes, including FGFR8, PROK2/PROKR2, NELF, CHD7 (responsible for CHARGE [coloboma of the eye, heart anomaly, choanal atresia, retardation, and genital and ear anomalies] syndrome, which includes hypogonadism in its phenotype), HS6ST1, WDR11, and SEMA3A, are associated with defects in neuronal migration that can result in Kallmann syndrome, but in most patients the affected gene remains undefined.

**Hypogonadotropic Hypogonadism Without Anosmia**

A specific genetic defect is not found in most cases of normosmic idiopathic hypogonadotropic hypogonadism (IHH) but the list of genes associated with this disorder is growing; mutations in the genes KISS1/KISS1R, TAC3/TACR3, and GNRH/GNRHR lead to abnormalities in the secretion and action of GnRH and are seen exclusively in patients with normosmic IHH. Mutations in FGFR1, FGFR8, PROK2, CHD7, and WDR11 more commonly present with anosmia/hyposmia (Kallmann syndrome), but are also associated with normosmic IHH in some cases. It appears that kisspeptin (the gene product of the KISS1 gene) and its G-protein–coupled receptor (GPR54) play an important role in triggering puberty in humans and act downstream of the leptin receptor in this pathway. Rare cases of leptin deficiency and leptin receptor defects are also associated with IHH. In addition, starvation and anorexia are associated with hypogonadism, most likely acting via the leptin pathway.

There are no known human mutations of the GnRH gene, but several families with mutations in the GnRH receptor have been described. These mutations account for 2-14% of idiopathic HH without anosmia. The severity of the defect is variable and many patients will respond to high-dose GnRH with increased gonadotropin secretion, indicating that the receptor defect is partial and not complete.

Mutations in gonadotropin genes are extremely rare. Mutations in the common α-subunit are not known in humans. Mutations in the LH-β subunit have been described in a few individuals and may lead to low, absent, or elevated LH levels, depending on the mutation. Defects in the FSH-β subunit may be the cause of azoospermia in a few rare cases.

Children with X-linked congenital adrenal hypoplasia have associated HH as a result of impaired GnRH secretion. In these patients, there is a mutation of the DAX1 gene at Xp21.2-21.3. Conditions occasionally associated with these patients because of the contiguous gene syndrome include glycerol kinase deficiency, Duchenne muscular dystrophy, and ornithine transcarbamoyltransferase deficiency. Most boys with DAX1 mutations develop HH in adolescence, although a patient with adult-onset adrenal insufficiency and partial HH and 2 females with HH and delayed puberty also have been described, the latter as part of extended families with males with classic HH. The DAX1 gene defect is, however, rare in patients with delayed puberty or HH without at least a family history of adrenal failure (see Chapter 576).

It should be noted that genotype–phenotype correlations in IHH appear to be complex and pedigrees with digenic or oligogenic inheritance have been described. The same genetic defect may be associated with Kallmann syndrome, normosmic IHH, additional birth defects, delayed normal puberty, or an apparently normal phenotype. This variability has been observed more frequently in kindreds with mutations in FGFR8/FGFR1 and in PROK2/PROKR2 ligand-receptor pairs, and may be from other interacting genes, epigenetic effects, or environmental factors.

**Other Disorders with Hypogonadotropic Hypogonadism**

HH has been observed in a few patients with polycystic ovarian syndrome, in some with elevated melatonin levels, and in those with a variety of other syndromes such as Bardet-Biedl, Prader-Willi, multiple lentigines, and several ataxia syndromes. In rare cases, HH is associated with complex chromosomal abnormalities.

**Hypogonadotropic Hypogonadism Associated with Other Pituitary Hormone Deficiencies**

Defects in pituitary transcription factors such as PROP-1, HESX-1, LHX-4, SOX-3, and LHX-3 lead to multiple pituitary deficiencies, including HH. Most of these present with multiple pituitary hormone deficiency in infancy, but some cases (especially with PROP-1 mutations) may present with hypogonadism or hypoadrenalism in adult life. Growth hormone is almost always affected in multiple pituitary hormone deficiency, but thyroid-stimulating hormone and adrenocorticotropic hormone may be spared in some cases. In patients with organic lesions in or near the pituitary, the gonadotropin deficiency is usually pituitary in origin. Microphallus (<2.5 cm at term) in the newborn male with growth hormone deficiency suggests the possibility of gonadotropin deficiency.

**DIAGNOSIS**

Levels of gonadotropins and gonadal steroids are elevated for up to 6 mo after birth (minipuberty), and if the diagnosis of HH is suspected in early infancy these levels will be found to be inappropriately low. By the second half of the 1st yr of life these levels normally decline to near zero and remain suppressed until late childhood. Therefore, routine lab tests cannot distinguish HH from normal suppression of gonadotropins in this age group. At the normal age of puberty, these patients fail to show clinical signs of puberty or normal increase in LH and FSH levels. Children with constitutional delay of growth and puberty will have the same clinical picture and similar lab findings (and these cases are far more common than true HH, especially in males), and their differentiation from patients with HH is extremely difficult. Dynamic testing with GnRH or hCG may not be able to distinguish these groups in a reliable manner. A testosterone level greater than 50 ng/dL (1.7 nmol/L) generally indicates that normal puberty is likely, but a lower level does not reliably distinguish these groups. At least 1 study shows that an inhibin B level of <35 pg/mL in Tanner stage 1 and <65 pg/mL in Tanner stage 2 may be able to distinguish IHH from constitutional delay in males.

Insulin-like growth factor-1, thyroid-stimulating hormone, free thyroxine, and morning cortisol levels should be checked to assess the status of other anterior pituitary hormones; dynamic testing for growth hormone deficiency and adrenal insufficiency may be necessary if these are abnormal or equivocal. HH is very likely if the patient has evidence of another pituitary deficiency, such as a deficiency of growth hormone, particularly if it is associated with adrenocorticotropic hormone deficiency. Hyperprolactinemia is a known cause of delayed puberty and should be excluded by determination of serum prolactin levels in all patients. The presence of anosmia usually indicates permanent gonadotropin deficiency, but occasional instances of markedly delayed puberty (18-20 yr of age) have been observed in anosmic individuals. Although anosmia may be present in the family or in the patient from early childhood, its existence is rarely volunteered, and direct questioning is necessary in all patients with delayed puberty. Formal olfactometry, such as the University of Pennsylvania Smell Identification Test, is advisable to determine if partial degrees of hyposmia are present because IHH patients display a broad spectrum of olfactory function.

In the absence of family history, it may not be possible to make the diagnosis of HH with certainty, but the diagnosis will become more and more likely as puberty is delayed further beyond the normal age. If pubertal delay persists beyond age 18 yr with low AM testosterone levels and inappropriately low gonadotropins (normal values are inappropriately low in this setting), then the patient can be presumptively diagnosed with HH. An MRI of the brain is indicated to look for...
mutations in various genes, including $FGFR1$, $PROK2$, $GNRH$, $CHD7$, and $TAC/TACR3$. Such recovery is more likely in patients who show an increase in testicular volume during treatment or when treatment has been discontinued. Therefore, a brief trial of interruption of treatment is justified in patients with idiopathic HH. However, the recovery of gonadal function may not be lifelong.

Bibliography is available at Expert Consult.

tumors and other anomalies in the hypothalamic-pituitary region. Genetic testing for pituitary transcription factors and several of the genes involved in isolated HH is also available and should be performed when possible. A renal ultrasound is recommended in patients with Kallmann syndrome because of its association with unilateral renal agenesis. Some authorities also recommend obtaining a baseline bone-density evaluation.

**Treatment**

**Constitutional delay of puberty** should be ruled out before a diagnosis of HH is established and treatment is initiated. Testicular volume of less than 4 mL by 14 yr of age occurs in approximately 3% of boys, but true HH is a rare condition. Even relatively moderate delays in sexual development and growth may result in significant psychologic distress and require attention. Initially, an explanation of the variations characteristic of puberty and reassurance suffice for the majority of boys. If by 15 yr of age no clinical evidence of puberty is beginning and the testosterone level is <50 ng/dL, a brief course of testosterone may be recommended. Various regimens are used, including testosterone enanthate 100 mg intramuscularly once monthly for 4-6 mo or 150 mg once monthly for 3 mo. Some practitioners use oral oxandrolone, which may have the theoretical advantage that it is not aromatized and may have less effect on bone age advancement (though definitive evidence of advantage is lacking). Oral oxandrolone may cause hepatic dysfunction and liver function tests should be monitored if it is used. Treatment is not necessary in all cases of constitutional delay, but if used, it is usually followed by normal progression through puberty and this may differentiate constitutional delay in puberty from isolated gonadotropin deficiency. The age of initiation of this treatment must be individualized.

Once a diagnosis of HH is made, treatment with testosterone will induce secondary sexual characteristics but will not stimulate testicular growth or spermatogenesis. Treatment with gonadotropins (either as a combination of hCG and human menopausal gonadotropins or using GnRH pulse therapy) will lead to testicular development, including spermatogenesis, but is much more complex to manage, so in most cases testosterone treatment is the best option. Either long-acting testosterone injections or daily application of testosterone gel may be used (testosterone patches have a high incidence of skin rash and are infrequently used in pediatrics). Testosterone enanthate or cypionate ester may be used in a starting dose of 25-50 mg injected intramuscularly every 3-4 wk, with 50 mg increments every 6-9 mo until a maintenance dose for adults (200-250 mg every 3-4 wk) is achieved. At that time, testosterone patches or testosterone gel may be substituted for the injections. Depending on patient and physician preference, transdermal testosterone may also be used as initial treatment instead of injections. For older boys, larger initial doses and increments can achieve more rapid virilization.

Treatment with gonadotropins is more physiologic but is expensive and complex, so it is less commonly used in adolescence. This treatment may be attempted in adult life when fertility is desired. The treatment schedule varies from 1,250-5,000 IU hCG in combination with 12.5-150 IU human menopausal gonadotropins 3 times per wk intramuscularly. It may require up to 2 yr of treatment to achieve adequate spermatogenesis in adults. Recombinant produced gonadotropins (LH and FSH) are also able to stimulate gonadal growth and function but are much more expensive. Treatment with GnRH (when available) is the most physiologically appropriate, but it requires the use of a subcutaneous infusion pump to deliver appropriately pulsed therapy because continuous exposure to GnRH will suppress gonadotropins rather than stimulate them. In some cases, patients with GnRH defects also have pituitary or testicular dysfunction (a “dual defect”) and may fail to respond adequately to GnRH or gonadotropin treatment. The rare patient with isolated LH deficiency can be treated effectively using hCG injections.

It has been found that up to 10% of patients diagnosed with HH (with or without anosmia) may exhibit spontaneous reversal of hypogonadism with sustained normal gonadal function when treatment has been discontinued; this may occur in patients with known genetic
Bibliography
Leydig cell tumors of the testes are rare causes of precocious pseudopuberty (gonadotropin-independent) and cause asymmetric enlargement of the testes. Leydig cells are sparse before puberty and tumors derived from them are more common in the adult, but rare cases do occur in children and the youngest reported case was in a 1 yr old boy. Although up to 10% of adult tumors may be malignant, metastasizing malignant tumors have not been reported in children, and pediatric Leydig cell tumors are usually unilateral and benign. Some tumors may be due to somatic activating mutations of the luteinizing hormone receptor.

The clinical manifestations are those of puberty in the male; onset usually occurs at 5-9 yr of age. Gynecomastia has been described. The tumor of the testis can usually be readily felt; the contralateral unaffected testis is normal in size for the age of the patient.

Plasma levels of testosterone are markedly elevated, and follicle-stimulating hormone and luteinizing hormone levels are suppressed. Ultrasonography may aid in the detection of small nonpalpable tumors. Fine-needle aspiration biopsy may help define the diagnosis.

Treatment consists of surgical removal of the affected testis. These tumors are generally resistant to chemotherapy. Progression of virilization ceases after removal of the tumor, and partial reversal of the signs of precocity may occur.

Testicular adrenal rests may develop into tumors that mimic Leydig cell tumors. Adrenal rest tumors are usually bilateral and occur in children with inadequately controlled congenital adrenal hyperplasia, usually of the salt-losing variety, during adolescence or young adult life. The stimulus for the growth of the adrenal rests is inadequate corticosteroid suppressive therapy causing excess adrenocorticotropic hormone secretion, and treatment with adequate doses almost always results in their regression. These tumors are histologically similar to primary Leydig cell tumors, but definite evidence of the origin of these may be achieved by demonstrating their 21-hydroxylase activity. Misdiagnosis of these tumors as primary Leydig cell tumors may lead to unnecessary orchidectomy and should be avoided.

Fragile X syndrome (see Chapter 81.5) is caused by the amplification of a polymorphic CGG repeat in the 5′ untranslated region of the FMRI gene at Xp17.3. The gene encodes an RNA binding protein that is highly expressed in the brain and the testis. In otherwise normal individuals, 6-50 CGG repeats are present in the gene; the presence of 50-200 repeats (permutation) is associated with mild intellectual disability and other abnormalities, and the presence of more than 200 repeats (fragile X mutation) is associated with the classic fragile X syndrome. Permutations are present in 1 in 1,000 white males, and
mutations are found in 1 in 4,000-8,000. A cardinal characteristic of the condition is testicular enlargement (macroorchidism), reaching 40-50 mL after puberty. Although the condition has been recognized in a child as young as 5 mo of age, affected boys younger than 6 yr of age rarely have testicular enlargement; by 8-10 yr of age, most have testicular volumes greater than 3 mL. The testes are enlarged bilaterally, are not nodular, and are histologically normal. Results of hormonal studies are normal. Direct DNA analysis searching for CGG repeat sequences permits definitive diagnosis.

Large-cell calcifying Sertoli cell tumors of the testes and sex cord tumors with annular tubules are extremely rare Sertoli cell tumors that may be a cause of breast development in young boys. These tumors are usually associated with Peutz-Jeghers syndrome or Carney complex; they often occur bilaterally, are multifocal, and are detectible by ultrasonography. Excessive production of aromatase (P450arom), the enzyme that converts testosterone to estradiol, causes feminization of these boys. Because they are usually benign, they may be left in place if they are not causing pain; the gynecomastia can be treated with aromatase inhibitors.

In boys with unilateral cryptorchidism, the contralateral testis is approximately 25% larger than normal for age. Testicular enlargement has also been noted in boys with Henoch-Schönlein purpura and lymphangiectasia. Epidermoid and dermoid cysts of the testes have been reported rarely.

Bibliography

Gynecomastia, the proliferation of mammary glandular tissue in the male, is a common condition. True gynecomastia (the presence of glandular breast tissue) needs to be distinguished from pseudogynecomastia, which is the result of accumulation of adipose tissue in the area of the breast that is commonly seen in overweight boys. True gynecomastia is characterized by the presence of a palpable fibroglandular mass at least 0.5 cm in diameter, located concentrically beneath the nipple and areolar region.

**PHYSIOLOGIC FORMS OF GYNECOMASTIA**

Gynecomastia occurs in many newborn males as a result of normal stimulation by maternal estrogen; the effect usually disappears in a few weeks. It is then extremely rare in prepubertal boys, in whom it should always be investigated to identify the cause, but again becomes common during normal puberty.

**Neonatal Gynecomastia**

Transient gynecomastia occurs in 60-90% of male newborns secondary to exposure to estrogens during pregnancy. Breast development may be asymmetrical and galactorrhea is seen in approximately 5%. Most cases resolve within 4-8 wk of birth, but a few can last as long as 12 mo.

**Pubertal Gynecomastia**

During early puberty to midpuberty, up to 70% of boys develop various degrees of subareolar hyperplasia of the breasts. Incidence peaks at 14 yr of age, at Tanner stage 3-4 and at a testicular volume of 5-10 mL. Physiologic pubertal gynecomastia may involve only 1 breast; it is not unusual for both breasts to enlarge at disproportionate rates or at different times. Tenderness of the breast is common but transitory. Spontaneous regression may occur within a few months; it rarely persists longer than 2 yr. Significant psychosocial distress may be present, especially in obese boys with relatively large breasts.

The cause is thought to be an imbalance between estrogen and androgen action at the level of breast tissue. Testing usually fails to reveal any significant difference in circulating estrogen and androgen levels between affected and unaffected males, but minor degrees of imbalance in free hormone levels may still be present. Other hormones, including leptin and luteinizing hormone, may directly stimulate breast development and may play a role in pubertal gynecomastia. Some cases may be caused by an increased sensitivity to estrogens and/or relative androgen resistance in the affected tissue. As androgen levels continue to rise in later puberty, most cases resolve.

**Pathologic Gynecomastia**

**See Table 585-1.**

**Monogenic forms of gynecomastia** are extremely rare, but do exist. Familial gynecomastia has occurred in several kindreds as an X-linked or autosomal dominant sex-limited trait. Some of these cases were found to be caused by constitutive activation of the P450 aromatase enzyme (CYP19A1 gene), leading to increased peripheral conversion of C-19 steroids to estrogens (increased aromatization). A report of this syndrome in a father and his son and daughter suggests autosomal dominant inheritance. Excess aromatase activity was shown in skin fibroblasts and transformed lymphocytes in vitro.

**Exogenous sources of estrogens** are an important cause of gynecomastia in prepubertal children. Very small amounts of estrogens can cause gynecomastia in male children and accidental exposure may occur by inhalation, percutaneous absorption, or ingestion. Common sources of estrogens include oral contraceptive pills and oral and transdermal estrogen preparations. Gynecomastia has been reported in workers involved in the manufacture of estrogens and even in the children of such workers. Gynecomastia can also occur secondary to exposure to medications that decrease the level of androgens (especially free androgens), increase estradiol, or displace androgens from breast androgen receptors. Spironolactone, alkylating agents, anabolic steroids, human chorionic gonadotropin, ketoconazole, cimetidine, and androgen inhibitors such as flutamide are all associated with the occurrence of gynecomastia. Weaker associations are seen with a large number of other medications and drugs of abuse, including opiates, alcohol, and marijuana, although the association with marijuana may not be as strong as previously thought. Lavender, tea oils, and excessive consumption of soy are also implicated as causes of prepubertal gynecomastia.

Klinefelter syndrome and other causes of male hypogonadism are strongly associated with gynecomastia. Significant gynecomastia is seen in 50% of adolescents with Klinefelter syndrome; it is also seen in other conditions characterized by male undervirilization, including partial androgen insensitivity syndrome and 17-β-hydroxysteroid reductase deficiency. Gynecomastia has also been observed in children with congenital virilizing adrenal hyperplasia (11β-hydroxylase deficiency) and with Leydig cell tumors of the testis or with feminizing tumors of the adrenal gland. Several boys with Peutz-Jeghers syndrome and gynecomastia had sex cord tumors of the testes. The testes may not be enlarged in these cases and the tumor is usually multifocal and bilateral. Excessive aromatase production accounts for the gynecomastia. When gynecomastia is associated with galactorrhea, a prolactinoma should be considered. Hyperthyroidism alters the androgen to estrogen ratio by increasing bound androgen and decreasing the free testosterone and may result in gynecomastia in up to 40% of cases. Gynecomastia is also seen in malnourished patients after restoration of normal nutrition (refeeding syndrome), in whom it may be from hepatic dysfunction or abnormal activation of the gonadotropin axis.

**EVALUATION OF GYNECOMASTIA**

In pubertal cases a detailed history and physical examination may be all that is needed to exclude rare pathologic causes. Historical evaluation should include family history of male relatives with gynecomastia, history of liver or renal disease, use of medications or drugs of abuse, and exposure to herbal and cosmetic products that may contain phytoestrogens. Physical examination should include special attention to the breasts (looking for overlying skin changes, fixation, local lymphadenopathy, and nipple discharge) as well as a testicular exam. No

Laboratory evaluation is indicated in routine cases with no other associated abnormality but all prepubertal cases, as well as pubertal cases with suspicious features, should be investigated; initial laboratory evaluation should include thyroid function tests (to rule out hyperthyroidism), testosterone, estradiol, human chorionic gonadotropin, luteinizing hormone, and prolactin levels. Most cases of hyperprolactinemia are associated with galactorrhea, but there are a few reports of hyperprolactinemia causing gynecomastia without associated galactorrhea. Because of circadian variation, these levels should ideally be obtained in the morning. Other tests that may be indicated in selected cases include a karyotype, dehydroepiandrosterone sulfate, and liver and renal function tests. Gonadotropin levels may be a useful screen for Klinefelter syndrome and will be elevated in pubertal boys with this condition. If elevated, a karyotype should be performed.

**TREATMENT**

Treatment in case of benign pubertal gynecomastia usually consists of reassuring the boy and his family of the physiologic and transient nature of the phenomenon. When the enlargement is striking and persistent and causes serious emotional disturbance to the patient, specific treatment may be justified. Unfortunately, medical treatment is generally ineffective in long-standing cases. Early cases respond better to medical treatment but it is harder to justify treatment as most cases will resolve spontaneously. Agents that have been used for medical treatment include androgens, aromatase inhibitors, and estrogen antagonists. The effectiveness of synthetic androgens is variable and side effects are a concern, so these are rarely used in pediatrics. Aromatase inhibitors make physiologic sense, but placebo-controlled trials have been disappointing. Estrogen antagonists like tamoxifen and raloxifene are more effective, with raloxifene being the superior agent in at least 1 well-designed trial. If medical treatment is attempted, it should be in early cases (<12 mo standing) using raloxifene (in a dose of 60 mg/day) or tamoxifen (10-20 mg/day) for 3-9 mo, with the understanding that success rates are generally low in severe cases and mild cases will likely resolve on their own without treatment.

In those cases where breast development is excessive (Tanner stages 3-5), causes significant psychologic distress, and fails to regress in 18-24 mo, surgical removal of the enlarged breast tissue may be indicated, particularly in boys who have completed or nearly completed pubertal development. Careful examination and laboratory testing to exclude nonphysiologic causes are advisable before proceeding to surgery.

Hypofunction of the ovaries can be either primary or central in etiology. It may be caused by congenital failure of development, postnatal destruction (primary or hypergonadotropic hypogonadism), or lack of central stimulation by the pituitary and/or hypothalamus (secondary or tertiary hypogonadotropic hypogonadism). **Primary ovarian insufficiency** (hypergonadotropic hypogonadism), which is also termed **premature ovarian failure**, is characterized by the arrest of normal ovarian function before the age of 40 yr. Certain genetic mutations can result in primary ovarian insufficiency. Hypofunction of the ovaries because of a lack of central stimulation (hypogonadotropic hypogonadism) can be associated with other processes, such as multiple pituitary hormone deficiencies and some chronic diseases. Table 586-1 details the etiologic classification of ovarian hypofunction.

**586.1 Hypergonadotropic Hypogonadism in the Female (Primary Hypogonadism)**

Diagnosis of hypergonadotropic hypogonadism before puberty is difficult. Except in the case of Turner syndrome, most affected patients have no prepubertal clinical manifestations.
TURNER SYNDROME

Turner described a syndrome consisting of sexual infantilism, webbed neck, and cubitus valgus in adult females (see Chapter 81). Ulrich described a girl with short stature and many of the same phenotypic features. The term Ulrich-Turner syndrome is frequently used in Europe, but is infrequently used in the United States where the condition is called Turner syndrome. The syndrome is defined as the combination of the characteristic phenotypic features accompanied by complete or partial absence of the second X chromosome with or without mosaicism.

Pathogenesis

Half the patients with Turner syndrome have a 45,X chromosomal complement. Approximately 15% of patients are mosaics for 45,X and a normal cell line (45,X/46,XX). Other mosaics with isochromosomes, 45,X/46,X,i(Xq); with rings, 45,X/46,X,r(X); or with fragments, 45,X/46,XX, occur less often. Mosaicism is detected most commonly without mosaicism.

Clinical Manifestations

Many patients with Turner syndrome are recognizable at birth because of a characteristic edema of the dorsa of the hands and feet and loose skinfolds at the nape of the neck. Low birthweight and decreased birth length are common (see Chapter 81). Clinical manifestations in childhood include webbing of the neck, a low posterior hairline, small mandible, prominent ears, epicantthal folds, high arched palate, a broad chest presenting the illusion of widely spaced nipples, cubitus valgus, and hyperconvex fingernails. The diagnosis is often first suspected at puberty when breast development fails to occur.

Short stature, the cardinal finding in virtually all girls with Turner syndrome, may be present with little in the way of other clinical manifestations. The linear growth deceleration begins in infancy and young childhood, gets progressively more pronounced in later childhood and adolescence, and results in significant adult short stature. Sexual maturation (breast development) fails to occur at the expected age; however, signs of adrenarche (pubic hair) are normally present. Among untreated patients with Turner syndrome, the mean adult height is 143-144 cm in the United States and most of northern Europe, but 140 cm in Argentina and 147 cm in Scandinavia (Fig. 586-1). The height is well correlated with the midparental height (average of the parents' heights). Specific growth curves for height have been developed for girls with Turner syndrome.

Associated cardiac defects are common. In the girls with Turner syndrome, life-threatening consequences of X-chromosome haplinsufficiency involve the cardiovascular system. There is a 4-5-fold increased rate of premature mortality secondary to congenital heart disease and premature coronary heart disease in adults with Turner syndrome. Clinically silent cardiac defects, mainly bicuspid aortic valve but also ascending aortic dilation, coarctation of the aorta, and partial anomalous pulmonary venous connections, are present in patients with Turner syndrome. Regardless of the age, all patients with Turner syndrome at the time of diagnosis need comprehensive cardiovascular evaluation by a cardiologist specializing in congenital heart disease. Complete cardiologic evaluation, including echocardiography, reveals isolated nonstenotic bicuspid aortic valves in one third to one half of patients. In later life, bicuspid aortic valve disease can progress to dilation of the aortic root. Less-frequent defects include aortic coarctation (20%), aortic stenosis, mitral valve prolapse, and anomalous pulmonary venous drainage. In 1 study, 38% of patients with 45,X chromosomes had cardiovascular malformations compared with 11% unknown, and the risk for the syndrome does not increase with maternal age. The genes involved in the Turner phenotype are X-linked genes that escape inactivation. A major locus involved in the control of linear growth has been mapped within the pseudoautosomal region of the X chromosome (PAR1). SHOX, a homeobox-containing gene of 170 kb of DNA within the PAR1, is thought to be important for controlling growth in children with Turner syndrome, Leri-Weill syndrome, and, rarely, in patients having idiopathic short stature. Genes for the control of normal ovarian function are postulated to be on Xp and perhaps 2 "supergenes" on Xq.

**Clinical Manifestations**

Many patients with Turner syndrome are recognizable at birth because of a characteristic edema of the dorsa of the hands and feet and loose skinfolds at the nape of the neck. Low birthweight and decreased birth length are common (see Chapter 81). Clinical manifestations in childhood include webbing of the neck, a low posterior hairline, small mandible, prominent ears, epicantthal folds, high arched palate, a broad chest presenting the illusion of widely spaced nipples, cubitus valgus, and hyperconvex fingernails. The diagnosis is often first suspected at puberty when breast development fails to occur.

Short stature, the cardinal finding in virtually all girls with Turner syndrome, may be present with little in the way of other clinical manifestations. The linear growth deceleration begins in infancy and young childhood, gets progressively more pronounced in later childhood and adolescence, and results in significant adult short stature. Sexual maturation (breast development) fails to occur at the expected age; however, signs of adrenarche (pubic hair) are normally present. Among untreated patients with Turner syndrome, the mean adult height is 143-144 cm in the United States and most of northern Europe, but 140 cm in Argentina and 147 cm in Scandinavia (Fig. 586-1). The height is well correlated with the midparental height (average of the parents' heights). Specific growth curves for height have been developed for girls with Turner syndrome.

Associated cardiac defects are common. In the girls with Turner syndrome, life-threatening consequences of X-chromosome haplinsufficiency involve the cardiovascular system. There is a 4-5-fold increased rate of premature mortality secondary to congenital heart disease and premature coronary heart disease in adults with Turner syndrome. Clinically silent cardiac defects, mainly bicuspid aortic valve but also ascending aortic dilation, coarctation of the aorta, and partial anomalous pulmonary venous connections, are present in patients with Turner syndrome. Regardless of the age, all patients with Turner syndrome at the time of diagnosis need comprehensive cardiovascular evaluation by a cardiologist specializing in congenital heart disease. Complete cardiologic evaluation, including echocardiography, reveals isolated nonstenotic bicuspid aortic valves in one third to one half of patients. In later life, bicuspid aortic valve disease can progress to dilation of the aortic root. Less-frequent defects include aortic coarctation (20%), aortic stenosis, mitral valve prolapse, and anomalous pulmonary venous drainage. In 1 study, 38% of patients with 45,X chromosomes had cardiovascular malformations compared with 11% unknown, and the risk for the syndrome does not increase with mater-
of those with mosaic monosomy X, the most common were aortic valve abnormalities and aortic coarctation. **Webbed neck in patients with or without recognized chromosome syndromes is associated with both flow-related and non-flow-related heart defects.** Among patients with Turner syndrome, those with webbed necks have a much greater chance of having coarctation of the aorta than those without webbed necks. Transthoracic echocardiogram in young girls is adequate if cardiac anatomy is clearly seen; otherwise magnetic resonance angiographic screening studies should be considered in asymptomatic individuals with Turner syndrome. During adolescence, and certainly before pregnancy (when possible) is contemplated, repeat cardiac evaluation should be considered even in those without prior findings of cardiac abnormalities. Blood pressure should be routinely monitored even in the absence of cardiac or renal lesions and especially in those with suggestions of aortic root dilation. Cardiac MRI is a valuable tool to detect and monitor aortic root dilation.

Renal ultrasound should be performed in all girls with Turner syndrome at diagnosis. One fourth to one third of patients have renal malformations on ultrasonographic examination (50% of those with 45,X karyotypes). The more serious defects include pelvic kidney, horseshoe kidney, double collecting system, complete absence of 1 kidney, and ureteropelvic junction obstruction. Some of the malformations may increase the risk of hypertension and urinary tract infection. Idiopathic hypertension is also common. Girls with Turner syndrome who had normal baseline renal ultrasound findings did not develop renal disease during a follow-up period averaging 6 yr.

When the ovaries were examined by ultrasonography, older studies found a significant decrease in percentage of detectable ovaries from infancy to later childhood. A subsequent report found no such age-related differences in a cross-sectional and longitudinal study; 27–46% of patients had detectable ovaries at various ages; 76% of those with X mosaicism and 26% of those with 45,X karyotypes had detectable ovaries. Sexual maturation usually fails to occur, but 10–20% of girls have spontaneous breast development, and a small percentage may have menstrual periods. Primary gonadal failure is associated with early onset of adrenal hyperplasia (elevation in dehydroepiandrosterone sulfate) but delayed pubarche (pubic hair development). Spontaneous pregnancies have been reported in menstruating patients with Turner syndrome. Premature menopause, increased risk of miscarriage, and offspring with increased risk of trisomy 21 have been reported. A woman with a 45,X/46,X,r(X) karyotype treated with hormone replacement therapy had 3 pregnancies, resulting in a normal 46,XY male infant, a spontaneous abortion, and a healthy term female with Turner syndrome 45,X/46,Xr(X).

Antithyroid antibodies (thyroid peroxidase, and/or thyroglobulin antibodies) occur in 30–50% of patients. The prevalence increases with advancing age. **Autoimmune thyroid disease,** with or without the presence of a goiter, occurs in 10–30% of patients. Age-dependent abnormalities in carbohydrate metabolism characterized by abnormal glucose tolerance and insulin resistance and, only rarely, frank type 2 diabetes occur in older patients with Turner syndrome. Impaired insulin secretion has been described in 45,X women. Cholesterol levels are elevated in adolescence, regardless of body mass index or karyotype.

**Inflammatory bowel disease,** both Crohn disease and ulcerative colitis, gastrointestinal bleeding because of abnormal mesenteric vasculature, and delayed gastric emptying time have all been reported. Screening for celiac disease is recommended by recent guidelines, as the risk of celiac disease is increased in Turner syndrome, with 4–6% of individuals affected. Although autoimmune diseases have been associated with Turner syndrome, the prevalence of type 1 diabetes with Turner syndrome is not very high.

**Sternal malformations** can be detected by lateral chest radiography. An increased carrying angle at the elbow is usually not clinically significant. Scoliosis occurs in approximately 10% of adolescent girls. Congenital hip dysplasia occurs more commonly than in the general population. Reported eye findings include anterior segment dysgenesis and keratoconus. Pigmented nevi become more prominent with age; melanocytic nevi are common. Essential hyperhidrosis, torus mandibularis, and alopecia areata occur rarely.

**Recurrent bilateral otitis media** develops in approximately 75% of patients. Sensorineural hearing deficits are common, and the frequency increases with age. Problems with gross and fine motor-sensory integration, failure to walk before 15 mo of age, and early language dysfunction often raise questions about developmental delay, but intelligence is normal in most patients. However, cognitive impairment does occur in patients with 45,X/46,X,r(X); the ring chromosome is unable to undergo inactivation and leads to 2 functional X chromosomes.

Special attention should be given to psychosocial development in girls with Turner syndrome. In general, the behavior function is normal in girls with Turner syndrome, but they are at an increased risk for social isolation, immaturity, and anxiety. Other conditions, such as dyslexia, nonverbal learning disability, and attention deficit disorder, have been reported in girls with Turner syndrome. In adults, deficits in perceptual spatial skills are more common than they are in the general population. Some unconfirmed data suggest the existence of an imprinted X-linked locus that affects cognitive function such as verbal and higher-order executive function skills. These functions are apparently better when the X is paternal in origin.

The prevalence of mosaicism depends in large part on the techniques used for studying chromosomal patterns. The use of fluorescent in situ hybridization and reverse transcription–polymerase chain reaction (PCR) has increased the reported prevalence of mosaic patterns to as high as 60–74%.

Mosaicism involving the Y chromosome occurs in 5%. A population study using PCR with 5 different primer sets found Y chromosome material in 12.2%. **Gonadoblastoma** among Y-positive patients occurred in 7–10%. Therefore, the recommendation is that prophylactic gonadectomy should be performed even in the absence of MRI or CT evidence of tumors. The recommended timing of this procedure is...
at the time of diagnosis, but this may need to be reevaluated in the future. The gonadoblastoma locus on the Y chromosome (GBY) maps close to the Y centromere. The presence of only the SRY (sex-determining region on the Y chromosome) locus is not sufficient to confer increased susceptibility for the development of gonadoblastoma. A detailed study of 53 patients with Turner syndrome by nested PCR excluded low-level Y mosaicism in almost all cases. A second round of PCR detected SRY on the distal short arm of the Y chromosome in only 2 subjects. Therefore, routine PCR for Y chromosome detection for the purpose of assigning gonadoblastoma risk is not indicated. High-throughput quantitative genotyping may provide an effective and inexpensive method for the identification of X chromosome abnormalities and Y chromosome material identification.

In patients with 45,X/46,XX mosaicism, the clinical abnormalities are attenuated and fewer; short stature is as frequent as it is in the 45,X patient and may be the only manifestation of the condition other than ovarian failure (see Fig. 586-1).

**Laboratory Findings**

Chromosomal analysis must be considered routinely in short girls. In a systematic search, using Southern blot analysis of leukocyte DNA, Turner syndrome was detected in 4.8% of girls referred to an endocrinology service because of short stature. Patients with a marker chromosome in some or all cells should be tested for DNA sequences at or near the centromere of the Y chromosome for GBY.

Ultrasoundography of the heart, kidneys, and ovaries is indicated after the diagnosis is established. The most common skeletal abnormalities are shortening of the 4th metatarsal and metacarpal bones, epiphyseal dysgenesis in the joints of the knees and elbows, Madelung deformity, scoliosis, and in older patients, inadequate osseous mineralization.

 Plasma levels of gonadotropins, particularly follicle-stimulating hormone (FSH), are markedly elevated to greater than those of age-matched controls during infancy; at 2-3 yr of age, a progressive decrease in levels occurs until they reach a nadir at 6-8 yr of age, and by 10-11 yr of age, they rise to adult castrate levels.

Antithyroid peroxidase and antithyroglobulin antibodies should be checked periodically, and if positive, levels of thyroxine and thyroid-stimulating hormone should be obtained. Turner syndrome girls should be screened for celiac disease by measuring tissue transglutaminase immunoglobulin A antibodies. Initial testing should be done around age 4 yr and repeated every 2-5 yr. Extensive studies have failed to establish that growth hormone deficiency plays a primary role in the pathogenesis of the growth disorder. Defects in normal secretory patterns of growth hormone are seen in adolescents because of a lack of gonadal steroids, but not in younger girls with Turner syndrome. In vitro, monocytes and lymphocytes show decreased sensitivity to insulin-like growth factor 1.

**Treatment**

Treatment with recombinant human growth hormone increases height velocity and ultimate stature in most, but not all, children with Turner syndrome. Many girls achieve heights of greater than 150 cm with early initiation of treatment. In a large, multicenter, placebo-controlled clinical trial, 99 patients with Turner syndrome who started receiving growth hormone at a mean age of 10.9 yr at doses between 0.27 and 0.36 mg/kg/wk achieved a mean height of 149 cm, with nearly one third reaching heights greater than 152.4 cm (60 in). In the Netherlands, higher doses of growth hormone (up to 0.63 mg/kg/wk in the 3rd yr of treatment) resulted in 85% of the subjects reaching adult heights in the normal range for the Dutch reference population. Growth hormone treatment should be initiated in early childhood and/or when there is evidence of height velocity attenuation on specific Turner syndrome growth curves. The average starting dose of growth hormone is 0.375 mg/kg/wk. Growth hormone therapy does not significantly aggravate carbohydrate tolerance and does not result in marked adverse events in patients with Turner syndrome. Serum levels of insulin-like growth factor 1 should be monitored if the patient is receiving high doses of growth hormone. If the insulin-like growth factor 1 levels are significantly elevated, the dose of growth hormone may need to be reduced. Treatment with growth hormone can cause excessive growth of the hands and feet in some girls with Turner syndrome.

Oxandrolone has also been used to treat the short stature associated with Turner syndrome, either alone or in combination with growth hormone. This synthetic anabolic steroid has weak androgenic effects, and patients should be monitored for signs of pubarche, as well as hepatotoxicity. The latter is rare.

Replacement therapy with estrogens is indicated, but there is little consensus about the optimal age at which to initiate treatment. The psychologic preparedness of the patient to accept therapy must be taken into account. The improved growth achieved by girls treated with growth hormone in childhood permits initiation of estrogen replacement at 12-13 yr. Delaying estrogen therapy to optimize height potential until 15 yr of age, as previously recommended, seems unwarranted. This change to starting earlier estrogen therapy was considered because of the psychologic importance of age-appropriate pubertal maturation. Also, delaying estrogen therapy could be deleterious for bone health and other aspects of the child's health. Low-dose estrogen replacement at 12 yr of age permits a normal pace of puberty without interfering with the positive effect of growth hormone on the final adult height. Estrogen therapy improves verbal and nonverbal memory in girls with Turner syndrome. In young women with age-appropriate pubertal development who achieve normal height, health-related quality-of-life questionnaires have yielded normal results.

Although many forms of estrogen are available, oral estrogens have been mostly used. Even though transdermal and injectable depot forms of estradiol may be alternative physiologic options, transdermal patches are increasing in popularity. This is because transdermal patches bypass the first hepatic metabolism, thereby requiring only a small amount of estrogen to attain the adequate levels for its function. For oral preparation a conjugated estrogen (Premarin), 0.15-0.625 mg daily, or micronized estradiol (Estrace), 0.5 mg given daily for 3-6 mo, is usually effective in inducing puberty. The recommendations for transdermal patch are 6.25 μg daily that is gradually increased over 2 yr to the adult dose of 100-200 μg daily. The estrogen then is cycled (taken on days 1-23) and a progestin (Provera) is added (taken on days 10-23) in a dose of 5-10 mg daily. In the remainder of the calendar month, during which no treatment is given, withdrawal bleeding usually occurs.

Prenatal chromosome analysis for advanced maternal age has revealed a frequency of 45,X/46,XX that is 10 times higher than when diagnosed postnatally. Most of these patients have no clinical manifestations of Turner syndrome, and levels of gonadotropins are normal. Awareness of this mild phenotype is important in counseling patients.

Psychosocial support for these girls is an integral component of treatment. A comprehensive psychologic education evaluation is recommended either at the time of Turner syndrome diagnosis, depending on the patient's age, when any of the components of behavior or cognition become obvious, or immediately preceding school entry. The Turner Syndrome Society, which has local chapters in the United States, and similar groups in Canada and other countries provide a valuable support system for these patients and their families in addition to that given by the healthcare team.

Successful pregnancies have been carried to term using ovum donation and in vitro fertilization. Adolescents with few signs of spontaneous puberty may have ovaries with follicles. There remains a future possibility of using cryopreserved ovarian tissue with immature oocytes before the regression of the ovaries for the future pregnancies. In adult women with Turner syndrome, there seems to be a high prevalence of undiagnosed bone mineral density, lipid, and thyroid abnormalities. Glucose intolerance, diminished 1st-phase insulin response, elevated blood pressure, and lowered fat-free mass are common. Glucose tolerance worsens, but fat-free mass and blood pressure and general physical fitness improve with sex hormone replacement. The neurocognitive profile of adult women is unaffected by estrogen status.

**XX Gonadal Dysgenesis**

Some phenotypically and genetically normal females have gonadal lesions identical to those in 45,X patients but without somatic features
of Turner syndrome; their condition is termed pure gonadal dysgenesis or pure ovarian dysgenesis.

The disorder is rarely recognized in prepubertal children because the external genitals are normal, no other abnormalities are visible, and growth is normal. At pubertal age, sexual maturation fails to take place. Plasma gonadotropin levels are elevated. Delay of epiphyseal fusion may result in a eunuchoid habitus. Pelvic ultrasonography reveals streak ovaries. Affected siblings, parental consanguinity, and failure to uncover mosaicism all point to female-limited autosomal recessive inheritance. The disorder appears to be especially frequent in Finland (1 in 8,300 liveborn girls). In this population, several mutations in the FSH receptor gene (on chromosome 2p) were demonstrated as the cause of the condition. FSH receptor gene mutations were not detected in Mexican women with 46,XX gonadal dysgenesis. In some patients, XX gonadal dysgenesis has been associated with sensorineural deafness (Perrault syndrome). A patient with this condition and concomitant growth hormone deficiency and virilization has also been reported. There may be distinct genetic forms of this disorder. Müllerian agenesis, or the Mayer-Rokitansky-Küster-Hauser syndrome, which is second to gonadal dysgenesis as the most common cause of primary amenorrhea, occurring in 1 in 4,000-5,000 females, has been reported in association with 46,XX gonadal dysgenesis in a 17 yr old adolescent with primary amenorrhea and lack of breast development. One case of dysgerminoma with syncytiotrophoblastic giant cells was reported. An 18 yr old woman with primary amenorrhea and an absence of müllerian-derived structures, unilateral renal agenesis, and clinical signs of androgen excess, a phenotype resembling the Mayer-Rokitansky-Küster-Hauser syndrome, was found to have a loss-of-function mutation in the WNT4 gene. Treatment consists of estrogen replacement therapy.

**45,X/46,XY GONADAL DYSGENESIS**

45,X/46,XY gonadal dysgenesis, also called mixed gonadal dysgenesis, has extreme phenotypic variability postnatally that may extend from a Turner-like syndrome to a male phenotype with a penile urethra; it is possible to delineate 3 major clinical phenotypes. Short stature is a major finding in all affected children. Ninety percent of prenatally diagnosed cases have a normal male phenotype.

Some patients have no evidence of virilization; they have a female phenotype and often have the somatic signs of Turner syndrome. The condition is discovered prepubertally when chromosomal studies are made in short girls, or later when chromosomal studies are made because of failure of sexual maturation. Fallopian tubes and uterus are present. The gonads consist of intraabdominal undifferentiated streaks; chromosomal study of the streak often reveals an XY cell line. The streak gonad differs somewhat from that in girls with Turner syndrome; their condition is termed mixed gonadal dysgenesis. In addition to wavy connective tissue, there are often tubular streak gonads. Plasma gonadotropin levels are elevated. Delay of epiphyseal fusion may result in a eunuchoid habitus. Pelvic ultrasonography reveals streak ovaries.

Some children have mild virilization manifested only by prepubertal clitoromegaly. Normal müllerian structures are present, but at puberty virilization occurs. These patients usually have an intraabdominal testis, a contralateral streak gonad, and bilateral fallopian tubes.

Many 45,X/46,XY children present with frank ambiguity of the genitals in infancy. A testis and vas deferens are found on one side in the labioscrotal fold, and a streak gonad is identified on the contralateral side. Despite the presence of a testis, fallopian tubes are often present bilaterally. An infantile or rudimentary uterus is almost always present.

Other genotypes and phenotypes have been described in mixed gonadal dysgenesis. Approximately 25% of 200 analyzed patients have a dicentric Y chromosome (45,X/46,X,Y dic Y). In some patients, the Y chromosome may be represented by only a fragment (45,X/45,X +f); application of Y-specific probes can establish the origin of the fragment. It is not clear why the same genotype (45,X/46,XY) can result in such diverse phenotypes. Mutations in the SRY gene have been described in some patients.

Children with a female phenotype present no problem in gender of rearing. Patients who are only slightly virilized are usually assigned a female gender of rearing before a diagnosis is established. Patients with ambiguity of the genitals are readily often clinically indistinguishable from patients with various types of 46,XY disorders of sex development (46,XY DSD). In some instances, there may need to be careful consideration regarding sex of rearing. Factors that may influence this decision include short stature, the need for surgical genital reconstruction, the presence of müllerian structures, and the need for gonadectomy because of predisposition of the gonad to the development of malignancy. In some patients followed to adulthood, the putative normal tests prove to be dysgenetic with eventual loss of Leydig and Sertoli cell function (see Chapter 583). In an analysis of 22 patients with mixed gonadal dysgenesis, no significant associations or correlations were found between internal and external phenotypes or endocrine function and gonadal morphologic features. The sex of rearing was determined by the appearance of the external genitalia. In 11 patients, basal and human chorionic gonadotropin–stimulated testosterone levels were lower than in control subjects.

Gonadal tumors, usually gonadoblastomas, occur in approximately 25% of these children. As described above, a gonadoblastoma locus has been localized to a region near the centromere of the Y chromosome (GBY). These germ cell tumors are preceded by the changes of carcinoma in situ. Accordingly, both gonads should be removed in all patients reared as girls, and the undifferentiated gonad should be removed in the patients reared as boys.

There is no correlation among the proportion of 45,X/46,XY cell lines in either blood or fibroblasts with the phenotype. In the past, all patients came to clinical attention because of their abnormal phenotypes. However, 45,X/46,XY mosaicism is found in approximately 7% of fetuses, with true chromosome mosaicism encountered prenatally. Of 76 infants with 45,X/46,XY mosaicism diagnosed prenatally, 72 had a normal male phenotype, 1 had a female phenotype, and only 3 males had hypospadias. Of 12 males whose gonads were examined, only 3 were abnormal. These data must be taken into account when counseling a family in which a 45,X/46,XY infant is discovered prenatally.

**XXX, XXXX, AND XXXXX FEMALES**

The 47,XXX (trisomy) chromosomal constitution is the most frequent extra–X chromosome abnormality in females, occurring in about 1 in 1,000 liveborn females. In 68%, this condition is caused by maternal meiotic nondisjunction, but most 45,X and half of 47,XXX constitutions are caused by paternal sex chromosome errors. The phenotype is that of a normal female; affected infants and children are not recognized based on the genital appearance.

Sexual development and menarche are normal. Most pregnancies have resulted in normal infants. By 2 yr of age, delays in speech and language become evident and lack of coordination, poor academic performance, and immature behavior are seen in some. These girls tend to be tall and gangly, manifest behavior disorders, and are placed in special education classes. Using high-resolution MRI, 10 47,XXX subjects had lower amygdala volumes than 20 euploid controls; 10 47,XXX subjects had even lower amygdala volumes. In a review of 155 girls, 62% were physically normal. There is marked variability within the syndrome, and a small proportion of affected girls are well coordinated, socially outgoing, and academically superior.

**XXXX and XXXXX Females**

The great majority of females with these rare karyotypes have been intellectually challenged. Commonly associated defects are epiphondal folds, hypertelorism, clinodactyly, transverse palmar creases, radioulnar synostosis, and congenital heart disease. Sexual maturation is often incomplete and may not occur at all. Nevertheless, 3 women with the tetra-X syndrome gave birth, but no pregnancies were reported in 49,XXXX women. Most 48,XXXX women tend to be tall, with an average height of 169 cm, whereas short stature is a common feature of the 49,XXXXX phenotype.

**NOONAN SYNDROME**

Girls with Noonan syndrome show certain anomalies that also occur in girls with 45,X Turner syndrome, but they have normal 46,XX chromosomes (see Chapter 81.4). The most common abnormalities are
OTHER OVARIAN DEFECTS

Some young women with no chromosomal abnormality are found to have streak gonads that may contain only occasional or no germ cells. Gonadotropins are increased. Cytotoxic drugs, especially alkylating agents such as cyclophosphamide and busulfan, procarbazine, etoposide, and exposure of the ovaries to irradiation for the treatment of malignancy are frequent causes of ovarian failure. Young women with Hodgkin disease demonstrate that combination chemotherapy and pelvic irradiation may be more deleterious than either therapy alone. Teenagers are more likely than older women to retain or recover ovarian function after irradiation or combined chemotherapy; normal pregnancies have occurred after such treatment. Treatment regimens may result in some ovarian damage in most girls treated for cancer. The median lethal dose for the human oocyte is estimated to be approximately 4 Gy; doses as low as 6 Gy have produced primary amenorrhea. Ovarian transposition before abdominal and pelvic irradiation in childhood can preserve ovarian function by decreasing the ovarian exposure to less than 4-7 Gy.

Autoimmune ovarian failure occurs in 60% of children older than 13 yr of age with type I autoimmune polyendocrinopathy (Addison disease, hypoparathyroidism, candidiasis). This condition, also known as polyglandular autoimmune disease type 1 is rare worldwide but not in Finland, where, as a result of a founder gene effect, it occurs in 1 in 25,000 people. The gene for this disorder is located on chromosome 21 and is associated with human leukocyte antigen (HLA) DR5. In patients with polyglandular autoimmune disease type 1 and ovarian failure, an association with HLA-A3 has been described. Affected girls may not develop sexually, or secondary amenorrhea may occur in young women. The ovaries may have lymphocytic infiltration or appear simply as streaks. Most affected patients have circulating steroid cell antibodies and autoantibodies to 21-hydroxylase. Among patients with polyglandular autoimmune syndromes, 5% were found to have hypogonadism.

The condition also occurs in young women as an isolated event or in association with other autoimmune disorders, leading to secondary amenorrhea (premature ovarian failure [POF]). It occurs in 0.2-0.9% of women younger than 40 yr of age. Premature ovarian failure is a heterogeneous disorder with many causes: chromosomal, genetic, enzymatic, infectious, and iatrogenic. When associated with autoimmune adrenal disease, steroid cell autoantibodies are always present. These antibodies react with P450sc, 17α-OH, or 21-OH enzymes. When associated with an entire host of endocrine and nonendocrine autoimmune diseases and not adrenal autoimmunity, steroid cell autoantibodies are rarely found. A second autoimmune disorder, often subclinical, is found in 10-39% of adult patients with POF. One 17 yr old with idiopathic thrombocytopenic purpura and 47,XXX chromosomes had autoimmune POF. Patients with POF do not have the neurocognitive defects found in Turner syndrome patients.

Galactosemia, particularly the classical form of the disease, usually results in ovarian damage, beginning during intrauterine life. Levels of FSH and luteinizing hormone (LH) are elevated early in life. Ovarian damage may be caused by deficient uridine diphosphate-galactose (see Chapter 582). The Denys-Drash syndrome, caused by a WT1 mutation, can result in ovarian dysgenesis.

Ataxia-telangiectasia may be associated with ovarian hypoplasia and elevated gonadotropins; the cause is unknown. Gonadoblastomas and dysgerminomas have occurred in a few girls.

Hypergonadotropic hypogonadism has been postulated to also occur because of the resistance of the ovary to both endogenous and exogenous gonadotropins (Savage syndrome). This condition occurs also in women with POE. Antiovary antibodies or FSH receptor abnormalities may cause this condition. Mutation of the FSH receptor gene has been reported as an autosomal recessive condition (see Chapter 582). A few females with 46,XX chromosomes presenting in primary amenorrhea with elevated gonadotropin levels were found to have inactivating mutations of the LH receptor gene. This suggests that LH action is needed for normal follicular development and ovulation. Other genetic defects associated with ovarian failure include mutations in FOXL2, GNAS, CYP17, and CYP19. Some data also suggest that mutations within the gene encoding transcription factor SF-1 are associated with early ovarian failure.

586.2 Hypogonadotropic Hypogonadism in the Female (Secondary Hypogonadism)

Alvina R. Kansra and Patricia A. Donohoue

Hypofunction of the ovaries can result from failure to secrete normal pulses of the gonadotropins LH (luteinizing hormone) and FSH. Hypogonadotropic hypogonadism may occur if the hypothalamic-pituitary-gonadal axis is interrupted either at the hypothalamic or pituitary level. The mechanisms that result in hypogonadotropic hypogonadism include failure of the hypothalamic luteinizing hormone–releasing hormone (also known as gonadotropin-releasing hormone) pulse generator or inability of the pituitary to respond with secretion of LH and FSH. It is often difficult to distinguish between marked constitutional delay and hypogonadotropic hypogonadism.

ETIOLOGY

Hypopituitarism

Hypogonadotropic hypogonadism is most commonly seen with multiple pituitary hormone deficiencies resulting from malformations (e.g., septooptic dysplasia, other midline defects), pituitary transcription factor defects such as in PROP-1, or lesions of the pituitary that are acquired postnatally. Familial isolated gonadotropin deficiency associated with anosmia (Kallmann syndrome) was described in 1944. Many other genetic causes for hypogonadotropic hypogonadism have been identified. A gene important in luteinizing hormone–releasing hormone secretion is named KISS (encoding the protein kisspeptin), which is suggested to play a significant role in the development of the luteinizing hormone–releasing hormone–secreting cells. Another set of genes recently implicated in hypogonadotropic hypogonadism are the genes for neurokinin B (TAC3) and its receptor (TAC3R).

In children with idiopathic hypopituitarism, the defect is usually found in the hypothalamus. In these patients, administration of gonadotropin-releasing hormone results in increased plasma levels of FSH and LH, establishing the integrity of the pituitary gland.

Hypogonadotropic hypogonadism is less common than hypergonadotropic hypogonadism. The latter condition, when associated with LH excess, underlies polycystic ovarian syndrome (Stein-Leventhal syndrome; see Chapter 552).

Isolated Deficiency of Gonadotropins

This heterogeneous group of disorders is characterized more fully with the use of the gonadotropin-releasing hormone analog stimulation test. In most children, the pituitary gland is normal, and the defect causing gonadotropin deficiency resides in the hypothalamus. Patients with hyperprolactinemia, most often caused by a pituitary prolactin-secreting adenoma, often have suppression of gonadotropin secretion. If breast development has occurred, then galactorrhea and amenorrhea are frequently seen.

Several sporadic instances of anosmia with hypogonadotropic hypogonadism have been reported. Anosmic hypogonadal females have
also been reported in kindreds with Kallmann syndrome, but hypogonadism more frequently affects the males in these families. Mutations in the gene for the β-subunit of FSH and LH have been reported.

Some autosomal recessive disorders, such as the Laurence-Moon-Biedl, multiple lentigines, and Carpenter syndromes, appear in some instances to include gonadotropic hormone deficiency. Patients with Prader-Willi syndrome usually have some degree of hypogonadotropic hypogonadism. Girls with severe thalassemia may have gonadotropin deficiency from pituitary damage caused by chronic iron overload secondary to multiple transfusions. Anorexia nervosa frequently results in hypogonadotropic hypogonadism. The rare patients described with leptin deficiency or leptin receptor defects have failure of pubertal maturation because of gonadotropin deficiency.

**DIAGNOSIS**

The diagnosis may be apparent in patients with other deficiencies of pituitary tropic hormones, but, as in males, it is difficult to differentiate isolated hypogonadotrophic hypogonadism from physiologic delay of puberty. Repeated measurements of FSH and LH, particularly during sleep, may reveal the rising levels that herald the onset of puberty. Stimulation testing with gonadotropin-releasing hormone or one of its analogs may help establish the diagnosis. Morbidity for both men and women with hypogonadism includes infertility and an increased risk of osteoporosis.

Pseudoprecocity Resulting from Lesions of the Ovary

Alvina R. Kansra and Patricia A. Donohoue

Chapter 587

Girls with signs of early puberty may, in rare circumstances, have a lesion of the ovary as the etiology. These include tumors or cysts that secrete estrogens, androgens, or both types of hormones. In these patients the sex steroid production is not mediated by pituitary gonadotropin secretion, and thus they are said to produce pseudoprecocity.

Ovarian tumors are rare in the pediatric population, occurring at a rate of less than 3 in 100,000. Most ovarian masses are benign, but 10-30% may be malignant. If they occur before 8 yr of age they may cause signs of puberty. Ovarian malignancies, the most common genital neoplasms in adolescence, account for only 1% of childhood cancers. More than 60% are germ cell tumors, most of which are dysgerminomas that can secrete tumor markers as well as sex hormones (see chapter 503). Five to 10% of germ cell tumors occur in phenotypic females with abnormal gonads associated with the presence of a Y chromosome. Next most common are epithelial cell tumors (20%), and nearly 10% are sex cord/stromal tumors (granulosa, Sertoli cell, and mesenchymal tumors). Multiple tumor markers can be seen in ovarian tumors, including α-fetoprotein, human chorionic gonadotropin, carcinoembryonic antigen, oncoproteins, p105, p53, KRAS mutations, cyclin D1, epidermal growth factor–related proteins and receptors, cathepsin B, and others. Variable levels of inhibin–activin subunit gene expression have been detected in ovarian tumors.

Functioning lesions of the ovary consist of benign cysts or malignant tumors. The majority synthesize estrogens; a few synthesize androgens. The most common estrogen-producing ovarian tumor causing precocious puberty is the granulosa cell tumor. Other tumors that can cause precocious puberty are thecomas, luteomas, mixed types, theca-lutein and follicular cysts, and ovarian tumors (i.e., teratoma, choriocarcinoma, and dysgerminoma).

ESTROGENIC LESIONS OF THE OVARY

These lesions cause isosexual precocious sexual development but account for only a small percentage of all cases of precocity. Benign ovarian follicular cysts are the most common tumors associated with isosexual precocious puberty in girls; they may rarely be gonadotropin dependent. Gonadotropin-independent follicular cysts that produce estrogen are often associated with the McCune-Albright syndrome.

Juvenile Granulosa Cell Tumor

In childhood, the most common neoplasm of the ovary with estrogenic manifestations is the granulosa cell tumor, although it makes up only 1-10% of all ovarian tumors. These tumors have distinctive histologic features that differ from those encountered in older women (adult granulosa cell tumor). The cells have high mitotic activity, follicles are often irregular, Call-Exner bodies are rare, and luteinization is frequent. The tumor may be solid or cystic, or both. It usually is benign. In a few instances, this tumor has been associated with multiple enchondromas (Ollier disease) and, in fewer still, with multiple subcutaneous hemangiomata (Maffucci syndrome).

Clinical Manifestations and Diagnosis

The juvenile granulosa cell tumor has been observed in newborns and may manifest with sexual precocity at 2 yr of age or younger; about half these tumors occurred before 10 yr of age. The mean age at diagnosis is 7.5 yr. The tumors are almost always unilateral. The breasts become enlarged, rounded, and firm, and the nipples prominent. The external genitals resemble those of a normal girl at puberty, and the uterus is enlarged. A white vaginal discharge is followed by irregular or cyclic menstruation. Ovulation, however, does not occur. The presenting manifestation may be abdominal pain or swelling. Pubic hair is usually absent unless there is mild virilization.

A mass is readily palpable in the lower portion of the abdomen in most children by the time sexual precocity is evident. The tumor may be small, however, and escape detection even on careful rectal and abdominal examination; the tumors may be detected by ultrasonography, but multidetector CT scans are most sensitive. Most such tumors (90%) are diagnosed at very early stages of malignancy.

Plasma estradiol levels are markedly elevated. Plasma levels of gonadotropins are suppressed and do not respond to gonadotropin-releasing hormone analog stimulation. Levels of antimüllerian hormone, inhibin B, and α-fetoprotein may be elevated. Activating mutations of Gsα are seen in 30%, and GATA-4 expression is retained in the more aggressive tumors while antimüllerian hormone levels are inversely proportional to tumor size. Osseous development is moderately advanced. Several case reports showing the association of 45,X/46,XY karyotype and ambiguous genitalia with ovarian granulosa tumor have been published in literature.

Treatment and Prognosis

The tumor should be removed as soon as the diagnosis is established. Prognosis is excellent because fewer than 5% of these tumors in children are malignant. Advanced-stage tumors, however, behave aggressively and require difficult decisions regarding surgical approaches as well as the use of irradiation and chemotherapy. In adults with granulosa cell tumors, p53 expression is associated with unfavorable prognosis. Vaginal bleeding immediately after removal of the tumor is common. Signs of precocious puberty abate and may disappear within a few months after the operation. The secretion of estrogens returns to normal.

Sex cord tumor with annular tubules is a distinctive tumor, thought to arise from granulosa cells, that occurs primarily in patients with Peutz-Jeghers syndrome. These tumors are multifocal, bilateral, and usually benign. The presence of calcifications aids ultrasonographic detection. Increased aromatase production by these tumors results in gonadotropin-independent precocious puberty. Inhibin A and B levels

Girls with signs of early puberty may, in rare circumstances, have a lesion of the ovary as the etiology. These include tumors or cysts that secrete estrogens, androgens, or both types of hormones. In these patients the sex steroid production is not mediated by pituitary gonadotropin secretion, and thus they are said to produce pseudoprecocity.

Ovarian tumors are rare in the pediatric population, occurring at a rate of less than 3 in 100,000. Most ovarian masses are benign, but 10-30% may be malignant. If they occur before 8 yr of age they may cause signs of puberty. Ovarian malignancies, the most common genital neoplasms in adolescence, account for only 1% of childhood cancers. More than 60% are germ cell tumors, most of which are dysgerminomas that can secrete tumor markers as well as sex hormones (see chapter 503). Five to 10% of germ cell tumors occur in phenotypic females with abnormal gonads associated with the presence of a Y chromosome. Next most common are epithelial cell tumors (20%), and nearly 10% are sex cord/stromal tumors (granulosa, Sertoli cell, and mesenchymal tumors). Multiple tumor markers can be seen in ovarian tumors, including α-fetoprotein, human chorionic gonadotropin, carcinoembryonic antigen, oncoproteins, p105, p53, KRAS mutations, cyclin D1, epidermal growth factor–related proteins and receptors, cathepsin B, and others. Variable levels of inhibin–activin subunit gene expression have been detected in ovarian tumors.

Functioning lesions of the ovary consist of benign cysts or malignant tumors. The majority synthesize estrogens; a few synthesize androgens. The most common estrogen-producing ovarian tumor causing precocious puberty is the granulosa cell tumor. Other tumors that can cause precocious puberty are thecomas, luteomas, mixed types, theca-lutein and follicular cysts, and ovarian tumors (i.e., teratoma, choriocarcinoma, and dysgerminoma).

ESTROGENIC LESIONS OF THE OVARY

These lesions cause isosexual precocious sexual development but account for only a small percentage of all cases of precocity. Benign ovarian follicular cysts are the most common tumors associated with isosexual precocious puberty in girls; they may rarely be gonadotropin dependent. Gonadotropin-independent follicular cysts that produce estrogen are often associated with the McCune-Albright syndrome.

Juvenile Granulosa Cell Tumor

In childhood, the most common neoplasm of the ovary with estrogenic manifestations is the granulosa cell tumor, although it makes up only 1-10% of all ovarian tumors. These tumors have distinctive histologic features that differ from those encountered in older women (adult granulosa cell tumor). The cells have high mitotic activity, follicles are often irregular, Call-Exner bodies are rare, and luteinization is frequent. The tumor may be solid or cystic, or both. It usually is benign. In a few instances, this tumor has been associated with multiple enchondromas (Ollier disease) and, in fewer still, with multiple subcutaneous hemangiomata (Maffucci syndrome).

Clinical Manifestations and Diagnosis

The juvenile granulosa cell tumor has been observed in newborns and may manifest with sexual precocity at 2 yr of age or younger; about half these tumors occurred before 10 yr of age. The mean age at diagnosis is 7.5 yr. The tumors are almost always unilateral. The breasts become enlarged, rounded, and firm, and the nipples prominent. The external genitals resemble those of a normal girl at puberty, and the uterus is enlarged. A white vaginal discharge is followed by irregular or cyclic menstruation. Ovulation, however, does not occur. The presenting manifestation may be abdominal pain or swelling. Pubic hair is usually absent unless there is mild virilization.

A mass is readily palpable in the lower portion of the abdomen in most children by the time sexual precocity is evident. The tumor may be small, however, and escape detection even on careful rectal and abdominal examination; the tumors may be detected by ultrasonography, but multidetector CT scans are most sensitive. Most such tumors (90%) are diagnosed at very early stages of malignancy.

Plasma estradiol levels are markedly elevated. Plasma levels of gonadotropins are suppressed and do not respond to gonadotropin-releasing hormone analog stimulation. Levels of antimüllerian hormone, inhibin B, and α-fetoprotein may be elevated. Activating mutations of Gsα are seen in 30%, and GATA-4 expression is retained in the more aggressive tumors while antimüllerian hormone levels are inversely proportional to tumor size. Osseous development is moderately advanced. Several case reports showing the association of 45,X/46,XY karyotype and ambiguous genitalia with ovarian granulosa tumor have been published in literature.

Treatment and Prognosis

The tumor should be removed as soon as the diagnosis is established. Prognosis is excellent because fewer than 5% of these tumors in children are malignant. Advanced-stage tumors, however, behave aggressively and require difficult decisions regarding surgical approaches as well as the use of irradiation and chemotherapy. In adults with granulosa cell tumors, p53 expression is associated with unfavorable prognosis. Vaginal bleeding immediately after removal of the tumor is common. Signs of precocious puberty abate and may disappear within a few months after the operation. The secretion of estrogens returns to normal.

Sex cord tumor with annular tubules is a distinctive tumor, thought to arise from granulosa cells, that occurs primarily in patients with Peutz-Jeghers syndrome. These tumors are multifocal, bilateral, and usually benign. The presence of calcifications aids ultrasonographic detection. Increased aromatase production by these tumors results in gonadotropin-independent precocious puberty. Inhibin A and B levels
are elevated and decrease after tumor removal. In 1 study, 9 of 13 sex cord/stromal tumors exhibited follicle-stimulating hormone receptor mutations, suggesting a role for such mutation in the development of these tumors.

Chorioepithelioma has been reported only rarely. This highly malignant tumor is thought to arise from a preexisting teratoma. The usually unilateral tumor produces large amounts of human chorionic gonadotropin, which stimulates the contralateral ovary to secrete estrogen. Elevated levels of human chorionic gonadotropin are diagnostic.

Follicular Cyst
Small ovarian cysts (<0.7 cm in diameter) are common in prepubertal children. At puberty and in girls with true isosexual precocious puberty, larger cysts (1-6 cm) are often seen; these are secondary to stimulation by gonadotropins. However, similar larger cysts occur occasionally in young girls with precocious puberty in the absence of luteinizing hormone and follicle-stimulating hormone. Because surgical removal or spontaneous involution of these cysts results in regression of pubertal changes, there is little doubt that they are its cause. The mechanism of production of these autonomously functioning cysts is unknown. Such cysts may form only once, or they may disappear and recur, resulting in waxing and waning of the signs of precocious puberty. They may be unilateral or bilateral. The sexual precocity that occurs in young girls with McCune-Albright syndrome is usually associated with autonomous follicular cysts caused by a somatic-activating mutation of the Gtα-protein occurring early in development (see Chapter 562.6). Gonadotropins are suppressed, and estradiol levels are often markedly elevated, but they may fluctuate widely and even temporarily may return to normal. Gonadotropin-releasing hormone analog stimulation fails to evoke an increase in gonadotropins. Ultrasonography is the method of choice for the detection and monitoring of such cysts. Aromatase inhibitors are shown to be the mainstay of the therapy in females with McCune-Albright syndrome and persistent estradiol elevation. A short period of observation to ascertain the lack of spontaneous resolution is advisable before cyst aspiration or cystectomy is considered. Cystic neoplasms must be considered in the differential diagnosis.

ANDROGENIC LESIONS OF THE OVARY
Virilizing ovarian tumors are rare at all ages but particularly so in prepubertal girls. Arrhenoblastoma has been reported as early as 14 days of age, but few cases have been reported in girls younger than 16 yr of age.

The gonadoblastoma occurs exclusively in dysgenetic gonads, particularly in phenotypic females who have a Y chromosome or a Y fragment in their genotype (46,XY; 45,X/46,XY; 45,X/46,X-fra). As noted above, there is a proposed gonadoblastoma locus on the Y chromosome (GBY). The tumors may be bilateral. Virilization occurs with some but not all tumors. The clinical features are the same as those seen in patients with virilizing adrenal tumors and include accelerated growth, acne, clitoral enlargement, and growth of sexual hair. A palpable, abdominal mass is found in about 50% of patients. Plasma levels of testosterone and androstenedione are elevated, and gonadotropins are suppressed. Ultrasonography, CT, and MRI usually localize the lesion. The dysgenetic gonad of phenotypic females with a Y chromosome or fragment of Y chromosome containing GBY should be removed prophylactically. When a unilateral tumor is removed, the contralateral dysgenetic gonad should also be removed. Association of gonadoblastoma and WAGR (Wilms, aniridia, genitourinary anomalies, mental retardation) syndrome is also reported in the literature. In an immunohistochemical study of 2 gonadoblastomas, expressions of WTI, p53, and MIS, as well as inhibin, were all demonstrated.

Virilizing manifestations occur occasionally in girls with juvenile granulosa cell tumors. Adrenal rests and hilum cell tumors rarely lead to virilization. Activating mutations of G-protein genes have been described in ovarian (and testicular) tumors. Gtα mutations, usually seen in gonadal tumors associated with McCune-Albright syndrome, were also noted in 4 of 6 Leydig cell tumors (3 ovarian, 1 testicular). Two granulosa cell tumors and 1 thecoma of 10 ovarian tumors studied were found to have GIP-2 mutations.

Sertoli-Leydig cell tumors, rare sex cord/stromal neoplasms, constitute less than 1% of ovarian tumors. The average age at diagnosis is 25 yr; less than 5% of these tumors occur before puberty. α-Fetoprotein levels may be mildly elevated. In one 12 mo old with Sertoli-Leydig cell tumor presenting with isosexual precocity the only detectable tumor marker was the serum inhibin level, with elevations in both A and B subunits. Five-year survival rates are 70-90%.

Of 102 consecutive patients who underwent surgery because of ovarian masses over a 15 yr period, the presenting symptoms were acute abdominal pain in 56% and abdominal or pelvic mass in 22%. Of 9 children whose cause for surgery was presumed malignancy, 3 had dysgerminomas, 2 had teratomas, 2 had juvenile granulosa cell tumors, 1 had a Sertoli-Leydig cell tumor, and 1 had a yolk sac tumor.

SEX DIFFERENTIATION

See also Chapter 582. In normal differentiation, the final form of all sexual structures is consistent with normal sex chromosomes (either XX or XY). A 46,XX complement of chromosomes as well as genetic factors such as DAX1 (dosage-sensitive/sex-reversal adrenal hypoplasia on the X chromosome), the signaling molecule WNT-4, and R-Spondin1 are among the many needed for the development of normal ovaries. Development of the male phenotype is potentially more complex. It requires a Y chromosome and, specifically, an intact SRY (sex-determining region on the Y chromosome) gene, which, in association with other genes such as SOX9, SF-1 (steroidogenic factor-1), WT1 (Wilms tumor 1), and others (see Chapter 582), directs the undifferentiated gonad to become a testis. Aberrant recombinations may result in X chromosomes carrying SRY, resulting in XX males, or Y chromosomes that have lost SRY, resulting in XY females. Epigenetic causes of abnormal sex differentiation have been shown in plants, invertebrates, and vertebrates, and will likely contribute to human disorders of sex development (DSDs) as well.

Antimüllerian hormone (AMH) causes the müllerian ducts to regress; in its absence, they persist as the uterus, fallopian tubes, cervix, and upper vagina. AMH activation in the testes may require the SF-1 gene. By about 8 wk of gestation, the Leydig cells of the testis begin to produce testosterone. During this critical period of male differentiation, testosterone secretion is stimulated by placental human chorionic gonadotropin (hCG), which peaks at 8-12 wk. In the latter half of pregnancy, lower levels of testosterone are maintained by luteinizing hormone (LH) secreted by the fetal pituitary. Testosterone produced locally initiates development of the ipsilateral wolffian duct into the epididymis, vas deferens, and seminal vesicle. Development of the external genitalia also requires dihydrotestosterone (DHT), the more active metabolite of testosterone. DHT is produced largely from circulating testosterone and is necessary to fuse the genital folds to form the penis and scrotum. DHT is also produced via an alternative biosynthetic pathway from androstanediol, and this pathway must be intact for normal and complete prenatal virilization to occur. A functional androgen receptor, produced by an X-linked gene, is required for testosterone and DHT to induce these androgen effects.

In the XX fetus with normal long and short arms of the X chromosome, the bipotential gonad develops into an ovary by about the 10th-11th wk. This occurs only in the absence of SRY, testosterone, and AMH and requires a normal gene in the dosage-sensitive/sex-reversal
locus DAX1, the WNT-4 molecule, and R-Spondin1. A female external phenotype develops in the absence of fetal gonads. However, the male phenotype development requires androgen production and action. Estrogen is unnecessary for normal prenatal sexual differentiation, as demonstrated by 46,XX patients with aromatase deficiency and by mice without estradiol receptors.

Chromosomal aberrations may result in ambiguity of the external genitalia. Conditions of aberrant sex differentiation may also occur with the XX or XY genotype. The appropriate term for what was previously called intersex is DSD. This term defines a condition “in which development of chromosomal, gonadal, or anatomical sex is atypical.” It is increasingly preferable to use the term “atypical genitalia” rather than “ambiguous genitalia.” Tables 588-1 and 588-2 compare previous terms with their revised etiologic classification nomenclature. Table 582-1 in Chapter 582 lists some of the genes that are mutated in various forms of DSD.

The definition of atypical or ambiguous genitalia, in a broad sense, is any case in which the external genitalia do not appear completely male or completely female. Although there are standards for genital size dimensions, variations in size of these structures do not always constitute ambiguity.

Development of the external genitalia begins with the potential to be either male or female (Fig. 588-1). Virilization of a female, the most common form of DSD, results in varying phenotypes (Fig. 588-2), that develop from the basic bipotential genital appearances of the embryo (Fig. 588-1).

### Diagnostic Approach to the Patient with Atypical or Ambiguous Genitalia

The appearance of the external genitalia is rarely diagnostic of a particular disorder, and thus does not often allow distinction among the various forms of DSD. The most common forms of 46,XX DSD are virilizing forms of congenital adrenal hyperplasia. It is important to note that in 46,XY DSD, the specific diagnosis is not found in up to 50% of cases; partial androgen insensitivity syndrome and pure gonadal dysgenesis are common identifiable etiologies in XY DSD. At 1 center with a large experience, the etiologies of DSD in 250 patients over 25 yr were compiled. The 6 most common diagnoses accounted for 50% of the cases. These included virilizing congenital adrenal hyperplasia (14%), androgen insensitivity syndrome (10%), mixed gonadal dysgenesis (8%), clitoral/labial anomalies (7%), hypogonadotropic hypogonadism (6%), and 46,XY small-for-gestational-age males with hypospadias (6%).

The relative lack of established diagnoses in 46,XY DSD and the resulting lack of specific management emphasizes the need for thorough diagnostic evaluations. These include biochemical characterization of possible steroidogenic enzymatic defects in each patient with genitalic ambiguity. The parents need counseling about the potentially complex nature of the baby’s condition, and guidance as to how to deal with their well-meaning but curious friends and family members. The

evaluation and management should be carried out by a multidisciplinary team of experts that includes pediatric endocrinology, pediatric surgery/urology, pediatric radiology, newborn medicine, genetics, and psychology. Once the sex of rearing has been agreed on by the family and team, treatment can be organized. Genetic counseling should be offered when the specific diagnosis is established.

After a complete history and physical exam, the common diagnostic approach includes multiple steps, described in the following outline. These steps are usually performed simultaneously rather than waiting for results of 1 test prior to performing another, because of the sensitive and sometimes urgent nature of the condition. Careful attention to the presence of physical features other than the genitalia is crucial, to determine if a diagnosis of a particular multisystem syndrome is possible. These are described in more detail in Chapters 588.1, 588.2, and 588.3 below. Table 588-3 summarizes many of the features of commonly encountered causes of DSD.

Diagnostic tests include the following:

1. Karyotype, with rapid determination of sex chromosomes (in many centers this is available within 24-48 hr)
2. Other blood tests
   a. Screen for congenital adrenal hyperplasia: cortisol biosynthetic precursors and adrenal androgens (particularly 17-hydroxyprogesterone and androstenedione for 21-hydroxylase deficiency, the most common form)
   b. Screen for androgens and their biosynthetic precursors
   c. Screen for gonadal response to gonadotropin in patients suspected of having testicular gonads: stimulation with injections of hCG; measure testosterone and DHT before and after hCG
   d. Molecular genetic analyses for SRY and other Y-specific loci
   e. Gonadotropin levels
3. The internal anatomy of patients with ambiguous genitalia can be defined with 1 or more of the following studies:
   a. Voiding cystourethrogram
   b. Endoscopic examination of the genitourinary tract
   c. Pelvic ultrasound; renal and adrenal ultrasound
   d. Pelvic CT or MRI
   e. Exploratory laparoscopy

### 588.1 46,XX DSD

**Patricia A. Donohoue**

In this condition, the genotype is XX and the gonads are ovaries but the external genitalia are virilized. There is no significant AMH production because the gonads are ovaries. Thus the uterus, fallopian tubes, and cervix develop. The varieties and causes of this condition are relatively few. Most instances result from exposure of the female fetus to excessive exogenous or endogenous androgens during intrauterine life. The changes consist principally of virilization of the external genitalia (clitoral hypertrophy and labioscrotal fusion).

### CONGENITAL ADRENAL HYPERPLASIA

See Chapter 576.1.

This is the most common cause of genital ambiguity and of 46,XX DSD. Females with the 21-hydroxylase and 11-hydroxylase defects are the most highly virilized, although minimal virilization also occurs with the type II 3β-hydroxysteroid dehydrogenase defect (see Fig. 588-1). Female patients with salt-losing congenital adrenal hyperplasia tend to have more virilization than do non–salt-losing patients. Masculinization may be so intense that a complete penile urethra results, and the patient may appear to be a male with bilateral cryptorchidism.

### AROMATASE DEFICIENCY

In genotypic females, the rare condition of aromatase deficiency during fetal life leads to 46,XX DSD and results in hypergonadotropic hypogonadism at puberty because of ovarian failure to synthesize estrogen.

Two 46,XX infants had enlargement of the clitoris and posterior labial fusion at birth. In 1 instance, maternal serum and urinary levels of estrogen were very low and serum levels of androgens were high. Cord serum levels of estrogen were also extremely low, but those of androgen were elevated. The second patient also had virilization of unknown cause since birth, but the aromatase deficiency was not diagnosed until 14 yr of age, when she had further virilization and failed to go into puberty. At that time, she had elevated levels of gonadotropins and androgens but low estrogen levels, and ultrasonography...
large ovarian cysts bilaterally. These 2 patients demonstrate the important role of aromatase in the conversion of androgens to estrogens. Additional female and male patients with aromatase deficiency as a consequence of mutations in the aromatase gene (CYP19) are known. Two siblings were described. The 28 yr old XX proband was 177.6 cm tall (+2.5 SD) after having received hormonal replacement therapy; her 24 yr old brother was 204 cm tall (+3.7 SD), and had a bone age of 14 yr. Low-dose estradiol replacement, carefully adjusted to maintain normal age-appropriate levels, may be indicated for affected females, even prepubertally.

**GLUCOCORTICOID RECEPTOR GENE MUTATION**

A 9 yr old girl with 46,XX disorder of sexual development, thought to be caused by 21-hydroxylase deficiency (congenital adrenal hyperplasia) since the age of 5 yr, had elevated cortisol levels both at baseline and after dexamethasone, hypertension, and hypokalemia, suggestive of the diagnosis of generalized glucocorticoid resistance. A novel homozygous mutation in exon 5 of the glucocorticoid receptor was demonstrated. In this Brazilian family, the condition was autosomal recessive.

Cytochrome P450 oxidoreductase, encoded by a gene on 7q11.2, is a cofactor implicated in combined P450C17 and P450C21 steroidogenic defects. Girls are born with ambiguous genitalia, but the virilization does not progress postnatally and androgen levels are normal or low. Boys may be born undervirilized. Both may exhibit bony abnormalities seen in Antley-Bixler syndrome. Conversely, in a series of Antley-Bixler syndrome patients, those with ambiguous genitalia and disordered steroidogenesis had cytochrome P450 oxidoreductase deficiency. Those without genital ambiguity with normal steroidogenesis had fibroblast growth factor receptor 2 (FGFR2) mutations. The cardinal features of Antley-Bixler syndrome include craniosynostosis, severe midface hypoplasia, proptosis, choanal atresia/stenosis, frontal bossing, dysplastic ears, depressed nasal bridge, radiohumeral synostosis, long bone fractures and femoral bowing, and urogenital abnormalities.

**VIRILIZING MATERNAL TUMORS**

Rarely, the female fetus has been virilized during fetal life by a maternal androgen-producing tumor. In a few cases, the lesion was a benign adrenal adenoma, but all others were ovarian tumors, particularly androblastomas, luteomas, and Krukenberg tumors (Table 588-4). Maternal virilization may be manifested by enlargement of the clitoris, acne, deepening of the voice, decreased lactation, hirsutism, and elevated levels of androgens. In the infant, there is enlargement of the clitoris of varying degrees, often with labial fusion. Mothers of children with unexplained 46,XX DSD should undergo physical examination and measurements of their own levels of plasma testosterone, dehydroepiandrosterone sulfate, and androstenedione.

**ADMINISTRATION OF ANDROGENIC DRUGS TO WOMEN DURING PREGNANCY**

Testosterone and 17-methyltestosterone have been reported to cause 46,XX DSD in some instances (see Table 588-4). The greatest number of cases has resulted from the use of certain prostegational compounds for the treatment of threatened abortion. These progestins have been replaced by nonvirilizing ones.

Infants with virilization and 46,XX chromosomes and caudal anomalies have been reported for whom no virilizing agent could be identified. In such instances, the disorder is usually associated with other congenital defects, particularly of the urinary and gastrointestinal tracts. Y-specific DNA sequences, including SRY, are absent. In 1 case, a scrotal raphe and elevated testosterone levels were found, but the cause remains unknown.

**Bibliography** is available at Expert Consult.

**588.2 46,XY DSD**

Patricia A. Donohoue

In this condition, the genotype is XY but the external genitalia are either not completely virilized, are ambiguous (atypical), or are completely female. When gonads can be found, they invariably contain testicular elements; their development ranges from rudimentary to normal. Because the process of normal virilization in the fetus is so complex, it is not surprising that there are many varieties and causes of 46,XY DSD. As noted earlier, the etiology of 46,XY DSD is not identified in approximately 50% of cases.

**DEFECTS IN TESTICULAR DIFFERENTIATION**

The first step in male differentiation is conversion of the bipotential gonad into a testis. In the XY fetus, if there is a deletion of the short arm of the Y chromosome or of the SRY gene, male differentiation does not occur. The phenotype is female; müllerian ducts are well developed because of the absence of AMH, and gonads consist of undifferentiated streaks. By contrast, even extreme deletions of the long arm of the Y chromosome (Yq–) have been found in normally developed males, most of whom are azoospermic and have short stature. This indicates that the long arm of the Y chromosome normally has genes that prevent these manifestations. In many syndromes in which the testes fail to differentiate, Y chromosomes are morphologically normal.

**Denys-Drash Syndrome**

The constellation of nephropathy with ambiguous genitalia and bilateral Wilms tumor is the major phenotype of this syndrome. Most reported cases have been 46,XY. Müllerian ducts are often present, indicating a global deficiency of fetal testicular function. Patients with a 46,XX karyotype have normal external genitalia. The onset of proteinuria in infancy progresses to nephrotic syndrome and end-stage renal failure by 3 yr of age, with focal or diffuse mesangial sclerosis being the most consistent histopathologic finding. Wilms tumor usually develops in children younger than 2 yr of age and is frequently bilateral. Gonadoblastomas have also been reported.

Several mutations of the WT1 gene, located on chromosome 11p13, have been found. WT1 functions as a tumor-suppressor gene and a transcriptional factor, and is expressed in the genital ridge and fetal gonads. Nearly all reported mutations have been near or within the zinc finger–coding region. One report found a zinc finger domain mutation in the WT1 alleles of a patient with no genitalicular abnormalities, suggesting that some cases of sporadic Wilms tumor may carry the WT1 mutation. Different mutations of the WT1 gene, con-

stidential heterozygote mutations at intron 9, have been described in Fraser syndrome, a condition of nonspecific focal and segmental glomerulosclerosis, 46,XY gonadal dysgenesis, and frequent gonadoblastoma, but without Wilms tumor.

WAGR Syndrome
This acronymic contiguous gene syndrome consists of Wilms tumor, aniridia, genitourinary malformations, and retardation (WAGR). These children have a deletion of 1 copy of chromosome 11p13, which may be visible on karyotype analysis. The deleted region encompasses the aniridia gene (PAX6) and the Wilms tumor-suppressor gene (WT1). Only the 46,XY males have genital abnormalities, ranging from cryptorchidism to severe deficiency of virilization. Gonadoblastomas have developed in the dysgenetic gonads. Wilms tumor usually occurs by 2 yr of age. Some cases also had unexplained obesity, raising the question of an obesity-associated gene in this region of chromosome 11 and naming the syndrome WAGRO.

Campomelic Syndrome
See Chapter 704.
This form of short-limbed dysplasia is characterized by anterior bowing of the femur and tibia, small, bladeless scapulae, small thoracic cavities, and 11 pairs of ribs, along with malformations of other organs. It is usually lethal in early infancy. Approximately 75% of reported 46,XY patients exhibit a completely female phenotype; the external and internal genitalia are female. Some 46,XY patients have ambiguous genitals. The gonads appear to be ovaries but histologically may contain elements of both ovaries and testes.

The gene responsible for the condition is SOX9 (SRY-related HMG [high-mobility group]-box gene) and is on 17q24-q25. This gene is structurally related to SRY and also directly regulates development of the type II collagen gene (COL2A1). The same mutations may result in different gonadal phenotypes. Gonadoblastoma was reported in a patient with this condition. The inheritance is autosomal dominant. Adrenal insufficiency and 46,XY gonadal dysgenesis has been described in patients with mutations of the SF-1 gene. In some of these patients, if the mother shares the SF-1 mutation, she has premature ovarian insufficiency.

46,XY sex reversal has been described in patients with deletions of parts of autosomal loci on chromosomes 2q, 9p, and 10q.

XY Pure Gonadal Dysgenesis (Swyer Syndrome)
The designation “pure” distinguishes this condition from forms of gonadal dysgenesis that are of chromosomal origin and associated with somatic anomalies. Affected patients have normal stature and a female phenotype, including vagina, uterus, and fallopian tubes, but at puberal age, breast development and menarche fail to occur. None of the other phenotypic features associated with 45,X are present. Patients present at puberty with hypergonadotropic primary amenorrhea. Familial cases suggest an X-linked or a sex-limited dominant autosomal transmission. Most of the patients examined have had mutations of the SRY gene. None had a SOX9 gene mutation. The gonads consist of almost totally undifferentiated streaks despite the presence of a cytogenetically normal Y chromosome. The primitive gonad cannot accomplish any testicular function, including suppression of müllerian ducts. There may be hilar cells in the gonad capable of producing some androgens; accordingly, some virilization, such as clitoral enlargement, may occur at the age of puberty. The streak gonads may undergo neoplastic changes, such as gonadoblastomas and dysgerminomas, and should be removed as soon as the diagnosis is established, regardless of the age of the patient.

Pure gonadal dysgenesis also occurs in XX individuals (see Chapter 586).

XY Gonadal Agenesis Syndrome (Embryonic Testicular Regression Syndrome)
In this rare syndrome, the external genitalia are slightly ambiguous but more nearly female. Hypoplasia of the labia; some degree of labioscrotal fusion; a small, clitoris-like phallus; and a perineal urethral opening are present. No uterus, no gonadal tissue, and usually no vagina can be found. At the age of puberty, no sexual development occurs and gonadotropin levels are elevated. Most children have been reared as females. In several patients with XY gonadal agenesis in whom no gonads could be found on exploration, significant rises in testosterone followed stimulation with hCG, indicating Leydig cell function somewhere. Siblings with the disorder are known.

It is presumed that testicular tissue was active long enough during fetal life for AMH to inhibit development of müllerian ducts but not long enough for testosterone production to result in virilization. In 1 patient, no deletion of the Y chromosome was found by means of Y-specific DNA probes. Testicular degeneration seems to occur between the 8th and the 12th fetal wk. Regression of the testis before the 8th wk of gestation results in Swyer syndrome; between the 14th and the 20th wk of gestation, it results in the rudimentary testis syndrome; and after the 20th wk, it results in anorchia.

In bilateral anorchia, sometimes referred to as vanishing testes syndrome, testes are absent, but the male phenotype is complete; it is presumed that tissue with fetal testicular function was active during the critical period of genital differentiation but that sometime later it was damaged. Bilateral anorchia in identical twins and unilateral anorchia in identical twins and in siblings suggest a genetic predisposition. Coexistence of anorchia and the gonadal agenesis syndrome in a sibship is evidence for a relationship between the disorders. SRY defects have not yet been reported for patients with anorchia.

A retrospective review of urologic explorations revealed absent testes in 21% of 691 testes. Of those, 73% had blind-ending cord structures with the suggested site of the vanishing testes being the inguinal canal (59%), abdomen (21%), superficial inguinal ring (18%), and scrotum (2%). It was suggested that the presence of cord structures on laparoscopy should prompt inguinal exploration because viable testicular tissue was found in 4 of these children. No hormonal data (hCG stimulation tests, AMH levels) were reported.

DEFECTS IN TESTICULAR HORMONES
Five genetic defects have been delineated in the enzymatic synthesis of testosterone by the fetal testis, and a defect in Leydig cell differentiation has been described. These defects produce 46,XY males with inadequate masculinization (see Fig. 582-1 in Chapter 582). Because levels of testosterone are normally low before puberty, an hCG stimulation test may be needed in children to assess the ability of the testes to synthesize testosterone.

Leydig Cell Aplasia
Patients with aplasia or hypoplasia of the Leydig cells usually have female phenotypes, but there may be mild virilization. Testes, epididymis, and vas deferens are present; the uterus and fallopian tubes are absent because of normal production of AMH. There are no secondary sexual changes at puberty, but pubic hair may be normal. Plasma levels of testosterone are low and do not respond to hCG; LH levels are elevated. The Leydig cells of the testes are absent or markedly deficient. The defect may involve a lack of receptors for LH. In children, hCG stimulation is necessary to differentiate the condition from the androgen insensitivity syndromes (AISs). There is male-limited autosomal recessive inheritance. The human LH receptor is a member of the G-protein-coupled superfamily of receptors that contains 7 transmembrane domains. Several inactivating mutations of the LH receptor have been described in males with hypogonadism suspected of having Leydig cell hypoplasia or aplasia.

High serum LH and low follicle-stimulating hormone were noted in 1 male with hypogonadism owing to a mutation in the gene for the β-subunit of follicle-stimulating hormone (see Table 583-1 in Chapter 583).

Lipoid Adrenal Hyperplasia
See Chapter 576.
The most severe form of congenital adrenal hyperplasia derives its name from the appearance of the enlarged adrenal glands resulting from accumulation of cholesterol and cholesterol esters. The rate-limiting process in steroidogenesis is the transport of free cholesterol.

through the cytosol to the inner mitochondrial membrane, where the P450 side-chain cleavage enzyme (P450scc; CYP11A1) acts. Cholesterol transport into mitochondria is mediated by the steroidogenic acute regulatory protein (STAR), whose synthesis occurs via cyclic adenosine monophosphate through a cyclic adenosine monophosphate response element–binding protein. STAR is a 30 kDa protein essential for steroidogenesis and is encoded by a gene on chromosome 8p11.2. The mitochondrial content of STAR increases between 1 and 5 hr after adrenocorticotropic hormone stimulation, long after the acute adrenocorticotropic hormone–induced increase in steroidogenesis. This has led some to suggest that extramitochondrial STAR might also be involved in the acute response to adrenocorticotropic hormone.

All serum steroid levels are low or undetectable, whereas corticosterone and plasma renin levels are quite elevated. The phenotype is female in both genetic females and males. Genetic males have no Müllerian structures because the testes can produce normal AMH but no steroid hormones. These children present with acute adrenal crisis and salt wasting in infancy. Most patients are 46,XX. In a few patients, ovarian steroidogenesis is present at puberty.

The regulatory role of STAR-independent steroidogenesis is illustrated by 46,XX 4 mo old twins with lipoid adrenal hyperplasia. One died at 15 mo because of cardiac complications related to coarctation of the aorta. The adrenal glands had characteristic lipid deposits. The surviving twin had spontaneous puberty with feminization at 11.5 yr and menarche at 13.8 yr. When restudied at the age of 15 yr, a homozygous frameshift-inactivating mutation in her STAR gene was discovered. This and the fact that she survived as an infant until 4 mo of age without replacement therapy with detectable serum aldosterone levels supports the hypothesis that STAR-independent steroidogenesis was able to proceed until enough intracellular lipid accumulated to destroy steroidogenic activity. Partial defects in only partially virilized males and delayed onset of salt wasting have been described. Complete P450scc defects may be incompatible with life because only this enzyme can convert cholesterol to pregnenolone, which then becomes progesterone, a hormone essential for the maintenance of normal mammalian pregnancy. Heterozygous mutation in CYP11A1 was described in a 4 yr old with 46,XY sex reversal and late-onset form of lipoid adrenal hyperplasia. At 6–7 wk of gestation, when maternal corpus luteum progesterone synthesis stops, the placenta, which does not express STAR, produces progesterone by STAR-independent steroidogenesis using the CYP11A1 enzyme system.

3β-Hydroxysteroid Dehydrogenase Deficiency

Males with this form of congenital adrenal hyperplasia (see Chapter 576) have various degrees of hypoplasias, with or without bifid scrotum and cryptorchidism and, rarely, a complete female phenotype. Affected infants usually develop salt-losing manifestations shortly after birth. Incomplete defects, occasionally seen in boys with premature puberty, as well as late-onset nonclassic forms, have been reported. These children have point mutations of the gene for type II 3β-hydroxysteroid dehydrogenase, resulting in impairment of steroidogenesis in the adrenals and gonads; the impairment may be unequal between adrenals and gonads. Normal pubertal changes in some boys could be possible without causing damage to the testis, epididymis, or vas deferens.

In the classical disorder, there is decreased synthesis of cortisol by the adrenals and of sex steroids by the adrenals and gonads. Levels of deoxycorticosterone and corticosterone are markedly increased and lead to the hypertension and hypokalemia characteristic of this form of male DSD. Although levels of cortisol are low, the elevated corticotropin and corticosterone levels prevent symptomatic cortisol deficiency. The renin–angiotensin axis is suppressed because of the strong mineralocorticoid effect of elevated deoxycorticosterone. Virilization does not occur at puberty; levels of testosterone are low, and those of gonadotropins are increased. Because fetal production of AMH is normal, no Müllerian duct remnants are present. In phenotypic XY females, gonadectomy and replacement therapy with hydrocortisone and sex steroids are indicated.

The defect follows autosomal recessive inheritance. Affected XX females are usually not detected until young adult life, when they fail to experience normal pubertal changes and are found to have hypertension and hypokalemia. This condition should be suspected in patients presenting with primary amenorrhea and hypertension whose chromosomal complement is either 46,XX or 46,XY.

**Deficiency of 17-Ketosteroid Reductase**

This enzyme, also called 17β-hydroxysteroid dehydrogenase, catalyzes the final step in testosterone biosynthesis. It is necessary to convert androstanedione to testosterone and also dehydroepiandrosterone to androstenediol and estrone to estradiol. Enzymatic defects in the fetal testis give rise to males with complete or near-complete female phenotype in 46,XY males. Müllerian ducts are absent, and a shallow vagina is present. The diagnosis is based on the ratio of androstenedione to testosterone; prepubertal children, stimulation with hCG may be necessary to make the diagnosis.

The defect is inherited in an autosomal recessive fashion. At least 4 different types of 17β-hydroxysteroid dehydrogenase are recognized, each coded by a different gene or different chromosomes. Type III is the enzyme defect that is especially common in a highly inbred Arab population in Gaza. The gene for the disorder is at 9q22 and is expressed only in the testes, where it converts androstenedione to testosterone. Most patients are diagnosed at puberty because of virilization and the failure to menstruate. Testosterone levels at puberty may approach normal, presumably as a result of peripheral conversion of androstenedione to testosterone; at this time, some patients spontaneously adopt a male gender role.

Type I 17β-hydroxysteroid dehydrogenase, encoded by a gene on chromosome 17q21, converts estrone to estradiol and is found in placenta, ovary, testis, liver, prostate, adipose tissue, and endometrium. Type II, whose gene is on chromosome 16q24, reverses the reactions of types I and III (converting testosterone to androstenedione and estrone to estradiol, respectively). Type IV is similar in action to type II. A late-onset form of 17-ketosteroid reductase deficiency presents with gynecomastia in young adult males.

**Persistent Müllerian Duct Syndrome**

In this disorder, there is persistence of Müllerian duct derivatives in otherwise completely virilized males. Cases have been reported in siblings and identical twins. Cryptorchidism is present in 80% of affected males; and during surgery for this or inguinal hernia, the condition is uncovered when a fallopian tube and uterus are found. The degree of Müllerian development is variable and may be asymmetric. Testicular function is normal in most, but testicular degeneration has been reported. Some affected males acquire testicular tumors after puberty. In a study of 38 families, 16 families had defects in the AMH gene, located on the short arm of chromosome 19. They had low AMH levels. In 16 families with high AMH levels, the defect was in the AMH type II receptor gene, with 10 of 16 having identical 27-bp deletions on exon 10 in at least 1 allele.

Treatment consists of removal of as many of the Müllerian structures as possible without causing damage to the testis, epididymis, or vas deferens.

**DEFECTS IN ANDROGEN ACTION**

In the following group of disorders, fetal synthesis of testosterone is normal and defective virilization results from inherited abnormalities in androgen action.
Dihydrotestosterone Deficiency

Decreased production of DHT in utero results in marked ambiguity of external genitalia of affected males. Biosynthesis and peripheral action of testosterone are normal.

The phenotype most commonly associated with this condition results in boys who have a small phallus, bifid scrotum, urogenital sinus with perineal hypospadias, and a blind vaginal pouch (Fig. 588-3). Testes are in the inguinal canals or labioscrotal folds and are normal histologically. There are no müllerian structures. Wolffian structures—the vas deferens, epididymis, and seminal vesicles—are present. Most affected patients have been identified as females. At puberty, virilization occurs; the phallus enlarges, the testes descend and grow normally, and spermatogenesis occurs. There is no gynecomastia. Beard growth is scanty, acne is absent, the prostate is small, and recession of the temporal hairline fails to occur. Virilization of the wolffian duct is caused by the action of testosterone itself, although masculinization of the urogenital sinus and external genitals depends on the action of DHT during the critical period of fetal masculinization. Growth of facial hair and of the prostate also appears to be DHT dependent.

The adult height reached is close to that of the father and other male siblings. There is significant phenotypic heterogeneity. This has led to a classification of such patients into 5 types of steroid 5α-reductase deficiency (SRD).

Several different gene defects of SRD5A2 (the 5α-reductase type 2 gene leading to SRD) have been identified, located on the short arm of chromosome 2, in patients from throughout the world. Familial clusters have been reported from the Dominican Republic, Turkey, Papua New Guinea, Brazil, Mexico, and the Middle East. There is no reliable correlation between genotype and phenotype.

The disorder is inherited as an autosomal recessive trait but is limited to males; normal homozygous females with normal fertility indicate that in females DHT has no role in sexual differentiation or in ovarian function later in life. The clinical diagnosis should be made as early as possible in infancy. It is important to distinguish this from partial androgen insensitivity syndrome (PAIS), as patients with PAIS are far less sensitive to androgen than are patients with SRD. The biochemical diagnosis of SRD is based on finding normal serum testosterone levels, normal or low DHT levels with markedly increased basal and especially hCG-stimulated testosterone: DHT ratios (>17), and high ratios of urinary etiocholanolone to androsterone. Children with androgen insensitivity have normal hepatic 5α reduction and, thus, a normal ratio of tetrahydrocortisol to 5α-tetrahydrocortisol, as opposed to those with SRD.

It is important to note that most but not all children with SRD reared as females in childhood have changed to male around the time of puberty. It appears that exposures to testosterone in utero, neonatally, and at puberty have variable contributions to the formation of male gender identity. Much more needs to be learned about the influences of hormones such as androgens as well as the influences of cultural, social, psychologic, genetic, and other biologic factors in gender identity and behavior. Infants with this condition should be reared as boys whenever practical. Treatment of male infants with DHT results in phallic enlargement.

Another cause of DHT deficiency is a block in an alternative pathway of DHT synthesis. Patients previously thought to have 46,XY DSD because of isolated 17,20-lyase deficiency have subsequently been characterized as having mutations in the AKR1C2 gene (3α-reductase type 3) or both the AKR1C2 and AKR1C4 (3α-reductase type 4) genes. These findings showed that both the classical and alternative pathways to DHT must be intact for normal prenatal virilization.

**Androgen Insensitivity Syndromes**

The AISs are the most common forms of male DSD, occurring with an estimated frequency of 1/20,000 genetic males. This group of heterogeneous X-linked recessive disorders is caused by more than 150 different mutations in the androgen receptor gene, located on Xq11-12: single point mutations resulting in amino acid substitutions or premature stop codons, frameshift and premature terminations, gene deletions, and splice-site mutations.

**Clinical Manifestations**

The clinical spectrum of patients with AISs, all of whom have a 46,XY chromosomal complement, range from phenotypic females (in complete AIS) to males with various forms of ambiguous genitalia and undervirilization (partial AIS, or clinical syndromes such as Reifenstein syndrome) to phenotypically normal-appearing males with infertility. In addition to normal 46,XY chromosomes, the presence of testes and normal or elevated testosterone and LH levels are common to all such children (Figs. 588-4 and 588-5).

**In complete androgen insensitivity syndrome (CAIS),** an extreme form of failure of virilization, genetic males appear female at birth and are invariably reared accordingly. The external genitalia are female. The vagina ends blindly in a pouch, and the uterus is absent as a result of the normal production and effect of AMH by the testes. In about one third of patients, unilateral or bilateral fallopian tube remnants are found. The testes are usually intraabdominal but may descend into the inguinal canal; they consist largely of seminiferous tubules. At puberty, there is normal development of breasts and the habitus is female, but menstruation does not occur and sexual hair is absent. Adult heights of these women are commensurate with those of normal males despite profound congenital deficiency of androgenic effects.

The testes of affected adult patients produce normal male levels of testosterone, which are converted to normal levels of DHT. Failure of normal male differentiation during fetal life reflects a defective response to androgens at that time. The absence of androgenic effects is caused by a striking resistance to the action of endogenous or exogenous testosterone at the cellular level.

Prepubertal girls with this disorder are often detected when inguinal masses prove to be testes or when a testis is unexpectedly found during herniorrhaphy. Approximately 1-2% of girls with an inguinal hernia prove to have this disorder. In infants, elevated LH levels should suggest the diagnosis. In older girls and adults, amenorrhea is the usual presenting symptom. In prepubertal children, the condition must
be differentiated from other types of XY undervirilized males in which there is complete feminization. These include XY gonadal dysgenesis (Swyer syndrome), true agonadism, Leydig cell aplasia including LH receptor defects, and 17-ketosteroid reductase deficiency; all these conditions, unlike CAIS, are characterized by low levels of testosterone as neonates and during adult life and by failure to respond to hCG during the prepubertal years.

Although patients with CAIS have unambiguously female external genitals at birth, those with PAIS have a wide variety of phenotypic presentations, ranging from perineoscrotal hypospadias, bifid scrotum, and cryptorchidism to extreme undervirilization appearing as clitoromegaly and labial fusion. Some forms of PAIS are known as specific syndromes. Patients with Reifenstein syndrome have incomplete virilization characterized by hypogonadism, severe hypospadias, and gynecomastia (see Fig. 588-5). Gilbert-Dreyfus and Lubs syndromes are also classified as PAISs. In all cases, abnormalities in the androgen receptor gene have been identified. Table 588-5 lists other causes of a PAIS-like syndrome.

**Diagnosis**

The diagnosis of patients with PAIS may be particularly difficult in infancy. The postnatal surge in testosterone and LH is diminished in those with CAIS but not in those with PAIS. In some, especially those sufficiently virilized in infancy, the diagnosis is not suspected until puberty when there is inadequate virilization with lack of facial hair or voice change and the appearance of gynecomastia. Azoospermia and infertility are common. Increasingly, androgen receptor defects are being recognized in adults who have a small phallus and testes and infertility. A single-amino-acid substitution in the androgen receptor was reported in a large Chinese family in whom some affected members were fertile while others had gynecomastia and/or hypospadias. Production of insulin-like growth factor 2 and insulin-like growth factor–binding protein–2, but not insulin-like growth factor–binding protein–3, by genital skin fibroblasts is decreased in CAIS compared with normal genital skin fibroblasts, suggesting a possible role for the insulin-like growth factor system in modulating androgen action.
Causes of a PAIS-Like Phenotype

**DEFECTS IN ANDROGEN PRODUCTION**
- Partial gonadal dysgenesis
- Mutations in SRY, NR5A1, WT1
- Mutations of the luteinizing hormone receptor
- Biosynthetic enzyme deficiencies
- 17,20-Lyase deficiency
- P450 oxidoreductase deficiency
- 17β-hydroxysteroid dehydrogenase deficiency type 3
- 5α-Reductase deficiency type 2

**GENETIC**
- Klinefelter syndrome
- Smith-Lemli-Opitz syndrome
- Denys-Drash syndrome
- Frasier syndrome

**PAIS**
- Mutations of the androgen receptor gene
- Normal androgen receptor gene with fetal growth restriction

**Treatment and Prognosis**

In patients with CAIS whose sexual orientation is unambiguously female, the testes should be removed as soon as they are discovered. Laparoscopic removal of Y chromosome–bearing gonads has been performed in patients with AIS and in those with gonadal dysgenesis. In one third of patients, malignant tumors, usually seminomas, develop by 50 yr of age. Several teenage girls have acquired seminomas. Replacement therapy with estrogens is indicated at the age of puberty. Normal breasts develop in affected girls who have not had their testes removed by the age of puberty. In these individuals, production of estradiol results from aromatase activity on testicular testosterone. The absence of androgenic activity also contributes to the feminization of these women.

The psychosexual and surgical management of patients with PAIS is extremely complex and depends in large part on the presenting phenotype. Osteopenia is recognized as a late feature of AIS.

Molecular analyses have suggested that phenotype may depend in part on somatic mosaicism of the androgen receptor gene. This was based on the case of a 46,XY patient who had a premature stop codon in exon 1 of the androgen receptor gene, but who also had evidence of virilization (pubic hair and clitoral enlargement) explained by the discovery of the wild-type allele on careful examination of the sequencing gel. The presence of mosaicism shifts the phenotype to a higher degree of virilization than expected from the genotype of the mutant allele alone.

Genetic counseling is difficult in families with androgen receptor gene mutation. In addition to lack of genotype–phenotype correlations, there is a high rate (27%) of de novo mutations in families.

Sex hormone–binding globulin reduction after exogenous androgen administration (stanozolol) correlates with the severity of the receptor defect and may become a useful clinical tool. Successful therapy with supplemental androgens has been reported in patients with PAIS and various mutations of the androgen receptor in the DNA-binding domain and the ligand-binding domain.

Mutated androgen receptors are also reported in patients with spinal and bulbar muscular atrophy in whom clinical manifestations including testicular atrophy, infertility, gynecomastia, and elevated LH, follicle-stimulating hormone, and estradiol levels usually manifest between the 3rd and 5th decades of life. Androgen receptor mutations have also been described in patients with prostate cancer.

**UNDETERMINED CAUSES**

Other XY undervirilized males display great variability of the external and internal genitalia and various degrees of phallic and müllerian development. Testes may be histologically normal or rudimentary, or there may only be 1. No recognized cause is identified in up to 50% of children with 46,XY DSD. Some ambiguity of the genitalia is associated with a wide variety of chromosomal aberrations, which must always be considered in the differential diagnosis, the most common being the 45,X/46,XY syndrome (see Chapter 586.1). It may be necessary to karyotype several tissues to establish mosaicism. Other complex genetic syndromes, many resulting from single gene mutations, are associated with varying degrees of ambiguity of the genitalia, particularly in the male. These entities must be identified on the basis of the associated extragenital malformations.

**Smith-Lemli-Opitz syndrome**

An autosomal recessive disorder caused by mutations in the sterol Δ7-reductase gene located on chromosome 11q12-q13. It is characterized by prenatal and postnatal growth retardation, microcephaly, ptosis, anteverted nares, broad alveolar ridges, syndactyly of the 2nd-3rd toes, and severe cognitive impairment (see Chapter 86.3). Its incidence is 1 in 20,000 to 30,000 live births in populations of northern and central European origin; 70% are male. Genotypic males usually have genital ambiguity and, occasionally, partial sex reversal with female genital ambiguity or complete sex reversal with female external genitals. Müllerian duct derivatives are usually absent. Affected 46,XX patients have normal genitalia. Two types of Smith-Lemli-Opitz syndrome have been recognized. The classical form (type I) described earlier and the acrodyssgenital syndrome, which is usually lethal within 1 yr and is associated with severe malformations, postaxial polydactyly, and extremely abnormal external genitalia (type II). Pyloric stenosis is associated with Smith-Lemli-Opitz syndrome type I and Hirschsprung disease with type II. Cleft palate, skeletal abnormalities, and 1 case of a lipoma of the pituitary gland have been seen in type II cases. Some authors believe in a spectrum of disease severity rather than in the above classification. Low plasma cholesterol with elevated 7-dehydrocholesterol, its precursor, are found in types I and II, and the levels do not correlate with severity. Maternal apolipoprotein E values do seem to correlate with severity. The most common prenatal expression of Smith-Lemli-Opitz syndrome is intrauterine growth retardation (see Chapter 86.3 for treatment).

46,XY DSD subjects also have been described in siblings with the α-thalassemia/mental retardation syndrome.

**588.3 Ovotesticular DSD**

Patricia A. Donohoue

In ovotesticular DSD, both ovarian and testicular tissues are present, either in the same or in opposite gonads. Affected patients have ambiguous genitalia, varying from normal female with only slight enlargement of the clitoris to almost normal male external genitalia (see Fig. 588-2A).

Approximately 70% of all patients have a 46,XX karyotype. Ninety-seven percent of affected patients of African descent are 46,XX. Fewer than 10% of persons with ovotesticular DSD are 46,XY. Approximately 20% have 46,XX/46,XY mosaicism. Half of these are derived from more than 1 zygote and are chimeras (chi 46,XX/46,XY). The presence of paternal and both maternal alleles for some blood groups is demonstrated. An ovotesticular DSD chimera, 46,XX/46,XY, was reported as resulting from embryo amalgamation after in vitro fertilization. Each embryo was derived from an independent, separately fertilized ovum.

Examination of 46,XX ovotesticular DSD patients with Y-specific probes has detected fewer than 10% with a portion of the Y chromosome including the SRY gene. Ovotesticular DSD is usually sporadic, but a number of siblings have been reported. The cause of most cases of ovotesticular DSD is unknown.

The most frequently encountered gonad in ovotesticular DSD is an ovotestis, which may be bilateral. If unilateral, the contralateral gonad

Bibliography is available at Expert Consult.
Bibliography

is usually an ovary but may be a testis. The ovarian tissue is normal, but the testicular tissue is dysgenetic. The presence and function of testicular tissue can be determined by measuring basal and hCG-stimulated testosterone levels as well as AMH levels. Patients who are highly virilized and have had adequate testicular function with no uterus are usually reared as males. If a uterus exists, virilization is often mild and testicular function minimal; assignment of female sex may be indicated. Selective removal of gonadal tissue inconsistent with sex of rearing may be indicated. In a few families, 46,XY ovotesticular DSD subjects and 44,XX males have been described in the same sibship.

Defects in R-Spondin1, encoded by the RSPO1 gene, have been described in 46,XX ovotesticular DSD.

Pregnancies with living offspring have been reported in 46,XX ovotesticular DSD individuals reared as females, but very few males with ovotesticular DSD have fathered children. Approximately 5% of patients will develop gonadoblastomas, dysgerminomas, or seminomas.

**DIAGNOSIS AND MANAGEMENT OF DISORDERS OF SEX DEVELOPMENT**

In the neonate, ambiguity of the genitals requires immediate attention to decide on the sex of rearing as early in life as possible. The family of the infant needs to be informed of the child’s condition as early, completely, compassionately, and honestly as possible. Caution must be used to avoid feelings of guilt, shame, and discomfort. Guidance needs to be provided to alleviate both short-term and long-term concerns and to allow the child to grow up in a completely supportive environment. The initial care is best provided by a team of professionals that include neonatologists and pediatric specialists, endocrinologists, radiologists, urologists, psychologists, and geneticists, all of whom remain focused foremost on the needs of the child. Management of the potential psychological upheaval that these disorders can generate in the child or the family is of paramount importance and requires physicians and other healthcare professionals with sensitivity, training, and experience in this field.

While awaiting the results of chromosomal analysis, pelvic ultrasonography is indicated to determine the presence of a uterus and ovaries. Presence of a uterus and absence of palpable gonads usually suggests a virilized XX female. A search for the source of virilization should be undertaken; this includes studies of adrenal hormones to rule out varieties of congenital adrenal hyperplasia, and studies of androgens and estrogens occasionally may be necessary to rule out aromatase deficiency. Virilized XX females are generally (but not always) reared as females even when highly virilized.

The absence of a uterus, with or without palpable gonads, often indicates an undervirilized male and an XY karyotype. Measurements of levels of gonadotropins, testosterone, AMH, and DHT are necessary to determine whether testicular production of androgen is present and is normal. Undervirilized males who are totally feminized may be reared as females. Certain significantly feminized infants, such as those with 5α-reductase deficiency, may be reared as males because these children virilize normally at puberty. Sixty percent of individuals with 5α-reductase deficiency assigned as female in infancy live as males as adults. An infant with a comparable degree of feminization resulting from an androgen receptor defect, such as CAIS, is best reared as a female.

When receptor disorders are suspected in the XY male with a small phallus (micropenis), a course of 3 monthly intramuscular injections of testosterone enanthate (25-50 mg) may assist in the differential diagnosis of androgen insensitivity, as well as in treatment.

In some mammals, the female exposed to androgens prenatally or in early postnatal life exhibits nontraditional sexual behavior in adult life. Most, but not all, girls who have undergone fetal masculinization from congenital adrenal hyperplasia or from maternal progesterin therapy have female sexual identity, although during childhood they may appear to prefer male playmates and activities over female playmates and feminine play with dolls in mothering roles.

In the past it was thought that surgical treatment of ambiguous genitalia to create a female appearance, particularly when a vagina is present, was more successful than construction of male genitalia. Considerable controversy exists regarding these decisions. Sexual functioning is to a large extent more dependent on neurohormonal and behavioral factors than the physical appearance and functional ability of the genitalia. Similarly, controversy exists regarding the timing of the performance of invasive and definitive procedures, such as surgery. Whenever possible without endangering the physical or psychological health of the child, an expert multidisciplinary team should consider deferring elective surgical repairs and gonadectomies until the child can participate in the informed consent for the procedure. One study of children (n = 59 boys and 18 girls) with gender dysphoria but without documentation of genomic or enzymologic abnormalities indicated that most of these children no longer have gender dysphoria after completion of puberty. Among those who do, homosexuality and bisexuality are the most frequent diagnoses.

For patients with DSD who have Y-chromosome material and intraabdominal gonads, gonadectomy is generally recommended because of the risk of gonadal tumors, many of which are malignant.

The pediatrician, pediatric endocrinologist, and psychologist, along with the appropriate additional specialists, should provide ongoing compassionate, supportive care to the patient and the patient’s family throughout childhood, adolescence, and adulthood. Support groups are available for families and patients with many of the conditions discussed.

### Bibliography

Diabetes mellitus (DM) is a common, chronic, metabolic disease characterized by hyperglycemia as a cardinal biochemical feature. The major forms of diabetes are differentiated by insulin deficiency vs insulin resistance: type 1 diabetes mellitus (T1DM) results from deficiency of insulin secretion because of pancreatic β-cell damage; type 2 diabetes mellitus (T2DM) is a consequence of insulin resistance occurring at the level of skeletal muscle, liver, and adipose tissue, with various degrees of β-cell impairment. T1DM is the most common endocrine-metabolic disorder of childhood and adolescence, with important consequences for physical and emotional development. Individuals with T1DM confront serious lifestyle alterations, including an absolute daily requirement for exogenous insulin, the need to monitor their own glucose level, and the need to pay attention to dietary intake. Morbidity and mortality stem from a constant potential for acute metabolic derangements and from long-term complications (usually in adulthood) that affect small and large blood vessels resulting in retinopathy, nephropathy, neuropathy, ischemic heart disease, and arterial obstruction with gangrene of the extremities. The acute clinical manifestations are caused by hypoinsulinemic hyperglycemic ketoadidosis; the genesis of T1DM owes to autoimmune mechanisms; and the long-term complications are related to metabolic disturbances (hyperglycemia).
DM is not a single entity but rather a heterogeneous group of disorders in which there are distinct genetic patterns as well as other etiologic and pathophysiologic mechanisms that lead to impairment of glucose tolerance. Table 589-1 presents a classification of diabetes and other categories of glucose intolerance. Three major forms of diabetes and several forms of carbohydrate intolerance are identified.

### TYPE 1 DIABETES MELLITUS
Formerly called insulin-dependent diabetes mellitus (IDDM) or juvenile diabetes, T1DM is characterized by low or absent levels of endogenously produced insulin and by dependence on exogenous insulin to prevent development of ketoacidosis, an acute life-threatening complication of T1DM. The natural history includes 4 distinct stages: (1) preclinical β-cell autoimmunity with progressive defect of insulin secretion, (2) onset of clinical diabetes, (3) transient remission “honeymoon period,” and (4) established diabetes during which there may occur acute and/or chronic complications and decreased life expectancy. The onset occurs predominantly in childhood, with a median age of 7-15 yr, but it may present at any age. The incidence of T1DM has steadily increased in nearly all parts of the world (Fig. 589-1). T1DM is characterized by autoimmune destruction of pancreatic islet β cells. Both genetic susceptibility and environmental factors contribute to the pathogenesis. Susceptibility to T1DM is genetically controlled by alleles of the major histocompatibility complex class II genes expressing human leukocyte antigens (HLAs). Autoantibodies to β-cell antigens such as islet cell cytoplasm (ICA), insulin autoantibody (IAA), antibodies to glutamic acid decarboxylase, and ICA512 are detected in serum from affected subjects. These can be detected months to years prior to clinical onset of T1DM. T1DM is associated with other autoimmune diseases such as thyroiditis, celiac disease, and Addison disease. In some children and adolescents with apparent T1DM, the β-cell destruction is not immune mediated. This subtype of diabetes occurs in patients of African or Asian origin and is distinct from known causes of β-cell destruction such as drugs or chemicals, viruses, mitochondrial gene defects, pancreatectomy, and ionizing radiation. These individuals may have ketoacidosis, but they have extensive periods of remission with variable insulin deficiency, similar to patients with T2DM.

### TYPE 2 DIABETES MELLITUS
Children and adolescents with this type of diabetes are usually obese but are not insulin dependent and infrequently develop ketosis. Some subjects with T2DM may present with or develop ketosis during severe infections or other stresses and may then need insulin for correction of symptomatic hyperglycemia. This category includes the most prevalent form of diabetes in adults, which is characterized by insulin...
resistance and often a progressive deficit in insulin secretion. This type of diabetes was formerly known as adult-onset diabetes mellitus or non–insulin-dependent diabetes mellitus.

The presentation of T2DM is typically more insidious than that with T1DM. In contrast to patients with T1DM who are usually ill at the time of diagnosis and whose presentation rarely spans more than a few weeks, children with T2DM often seek medical care because of excessive weight gain and fatigue as a result of insulin resistance and/or the incidental finding of glycosuria during routine physical examination. A history of polyuria and polydipsia is not always a cardinal clinical feature in these patients. The incidence of T2DM in children has increased by more than 10-fold, depending on geography and mostly as a result of the epidemic of childhood obesity (see Chapter 47). Pediatric T2DM may account for as many as 80% of the new cases of diabetes, especially in obese African-American and Mexican-American adolescents. Acanthosis nigricans (dark pigmentation of skin creases in the nape of the neck especially), a sign of insulin resistance, is present in the majority of patients with T2DM and is accompanied by a relative hyperinsulinemia at the time of the diagnosis (see Chapter 652). However, the serum insulin elevation is usually disproportionately lower than that of age-, weight-, and sex-matched non-diabetic children and adolescents, suggesting a state of insulin insufficiency. In some individuals, it may represent slowly evolving T1DM.

In some children with a strong family history of diabetes, impaired glucose tolerance (IGT) may occur in a pattern implying dominant inheritance. This pattern of diabetes has been termed maturity-onset diabetes of the young (MODY): it may require insulin treatment, can be treated with sulfonylureas with varying degrees of success, and is often now referred to as monogenic diabetes. MODY may present with glucose intolerance (IGT) that is intermediate between normal glucose homeostasis and diabetes. The term impaired glucose tolerance (IGT) refers to a metabolic stage that is intermediate between normal glucose homeostasis and diabetes. A fasting glucose concentration of 99 mg/dL (5.5 mmol/L) is the upper limit of “normal.” This choice is near the level above which acute-phase insulin secretion is lost in response to intravenous administration of glucose and is associated with a progressively greater risk of the development of microvascular and macrovascular complications.

Many individuals with IGT (fasting glucose 100-125 mg/dL) are euglycemic in their daily lives and may have normal or nearly normal glycated hemoglobin levels. Individuals with IGT often manifest hyperglycemia only when challenged with the oral glucose load used in the standardized oral glucose tolerance test.

In the absence of pregnancy, IGT is not a clinical entity but rather a risk factor for future diabetes and cardiovascular disease. This may be observed as an intermediate stage in any of the disease processes listed in Table 589-1. IGT is often associated with the insulin

---

**Figure 589-1** Incidence of type 1 diabetes in children ages 0-14 yr, by geographical region and over time. A, Estimated global incidence of type 1 diabetes, by region, in 2011. B, Time-based trends for the incidence of type 1 diabetes in children ages 0-14 yr in areas with high or high-intermediate rates of disease. (From Atkinson MA, Eisenbarth GS, Michels AW: Type 1 diabetes. Lancet 383:69–78, 2014, Fig. 1, p. 70.)
in 100,000 among youth younger than 10 yr and 18.6 in 100,000 of those older than 10 yr. It is estimated that 30,000 new cases occur each year in the United States, affecting 1 in 300 children and as many as 1 in 100 adults during the life span. Rates are similar or higher in most Western European countries and significantly lower in Asia and Africa.

Girls and boys are almost equally affected, but there is a modest female preponderance in some low-risk populations (e.g., the Japanese); there is no apparent correlation with socioeconomic status. Peaks of presentation occur in 2 age groups: at 5-7 yr of age and at the time of puberty. The first peak may correspond to the time of increased exposure to infectious agents coincident with the beginning of school; the second peak may correspond to the pubertal growth spurt induced by gonadal steroids and the increased pubertal growth hormone secretion (which antagonizes insulin). The understanding of the cause of diabetes or of its increased incidence remains elusive. A growing number of cases are presenting between 1 and 2 yr of age, especially in high-risk groups; the average age of presentation is older in low-risk populations. Low-risk groups that migrate to a high-risk country seem to acquire the increased risk of that country. On the other hand, there can be marked differences in incidence rates in various ethnic groups within the same country; for example, incidence rates in the 10-14 yr age group in the United States range from a low of 7.1 in Native Americans, to 17.6 in Hispanics, 19.2 in African-Americans, and 32.9 in whites. These variations also remain unexplained at this time.

**GENETICS**

There is a clear familial clustering of T1DM, with prevalence in siblings approaching 6%, whereas the prevalence in the general population in the United States is only 0.4%. Risk of diabetes is also increased when a parent has diabetes and this risk differs between the 2 parents; the risk is 3-4% if the mother has diabetes but 5-6% when the father has diabetes. In monozygotic twins, the concordance rate ranges from 30-65%, whereas dizygotic twins have a concordance rate of 6-10%. Because the concordance rate of dizygotic twins is higher than the sibling risk, factors other than the shared genotypes (e.g., the shared intrauterine environment) may play a role in increasing the risk in dizygotic twins. Furthermore, the genetic susceptibility for T1DM in the parents of a child with diabetes is estimated at 3%. It should be kept in mind that although there is a large genetic component in T1DM, 85% of newly diagnosed type 1 diabetic patients do not have a family member with T1DM. Thus, we cannot rely on family history to identify patients who may be at risk for the future development of T1DM as most cases will develop in individuals with no such family history.

**Type 1 Diabetes Mellitus (Immune Mediated)**

Brita M. Svoren and Nicholas Jospe

**Epidemiology**

T1DM accounts for approximately 10% of all cases of diabetes, affecting up to 3 million people in the United States and more than 15 million people in the world. Using population-based estimates of diabetes incidence and prevalence, a recent study indicates that approximately 15,000 youths are diagnosed with type 1 diabetes each year. While it accounts for most cases of diabetes in childhood, it is not limited to this age group; new cases continue to occur in adult life and approximately 50% of individuals with T1DM present as adults. The incidence of T1DM is highly variable among different ethnic groups (see Fig. 589-1). The overall age-adjusted incidence of T1 DM varies from 0.7 in 100,000 per yr in Karachi (Pakistan) to more than 40 in 100,000 per yr in Finland. The incidence of T1DM is increasing in most (but not all) populations and this increase appears to be most marked in populations where the incidence of autoimmune diseases was historically low. Data from Western European diabetes centers suggest that the annual rate of increase in T1DM incidence is 2-5%, whereas some central and eastern European countries demonstrate an even more rapid increase—up to 9%. The rate of increase is greatest among the youngest children. In the United States, the overall prevalence of diabetes among school-age children is approximately 1.9 in 1,000, increasing from a prevalence of 1 in 1,430 children at 5 yr of age to 1 in 360 children at 16 yr of age. Among African-Americans, the occurrence of T1DM is 30-60% of that seen in American whites. The annual incidence of new cases in the United States is now approximately 19.7
The major histocompatibility complex is a large genomic region that contains a number of genes related to immune system function in humans. These genes are further divided into HLA classes I, II, III, and IV genes. Class II genes are the ones most strongly associated with risk of T1DM, but some of the risk associated with various HLA types is a result of variation in genes in HLA classes other than class II. Overall, genetic variation in the HLA region can explain 40-50% of the genetic risk of T1DM (Fig. 589-2).

Some of the known associations include the HLA DR3/4-DQ2/8 genotype; compared to a population prevalence of T1DM of approximately 1 in 300, DR3/4-DQ2/8 newborns from the general population have a 1 in 20 genetic risk. This risk of development of T1DM is even higher when the high-risk HLA haplotypes are shared with a sibling or parent with T1DM. Thus, if a sibling has T1DM and shares the same high-risk DR3/4-DQ2/8 haplotype with another sibling, then the risk of autoimmunity in the other sibling is 50%. And this approach achieves 80% when siblings share both HLA haplotypes identical by descent. This is known as the relative paradox and points to the existence of other shared genetic risk factors (most likely in the extended HLA haplotype).

With advances in genotyping, further discrimination is possible and we can identify more specific risk ratios for specific haplotypes. For example, the DRB1*0401-DQA1*0301-DQB1*0302 haplotype has an odds ratio (OR) of 8.39 whereas the DRB1*0401-DQA1*0301-DQB1*0201 (high risk for diabetes) allele has an OR of 0.35, implicating the DQB1*0302 allele as a critical susceptibility allele. There are some dramatically protective DR-DQ haplotypes (e.g., DRB1*1501-DQA1*0102-DQB1*0602 [OR = 0.03], DRB1*1401-DQA1*0101-DQB1*0503 [OR = 0.02], and DRB1*0701-DQA1*0201-DQB1*0303 [OR = 0.02]). The DR2 haplotype (DRB1*1501-DQA1*0102-DQB1*0602) is dominantly protective and is present in 20% of the general population but is seen in only 1% of patients with T1DM.

### Role of Aspartate at Position 57 in DQB1
DQB1*0302 (high risk for diabetes) differs from DQB1*0201 (protective against diabetes) only at position 57, where it lacks an aspartic acid residue. The DQB1*0201 allele (increased risk for diabetes) also lacks aspartic acid at position 57, and it has been proposed that the presence of aspartate at this position alters the protein recognition and protein binding characteristics of this molecule. Although the absence of aspartate at this position appears to be important in most studies on white individuals, it does not have the same role in Korean and Japanese populations. Moreover, certain low-risk DQB1 genotypes also lack aspartic acid at position 57, including DQB1*0302/DQB1*0201 (DR7) and DQB1*0201 (DR3)/DQB1*0201 (DR7). Thus, the presence of aspartate at this position is usually, but not always, protective in white populations but not necessarily in other populations.

### Role of Human Leukocyte Antigen Class I
Although the alleles of class II HLA genes appear to have the strongest associations with diabetes, recent genotyping studies and analyses of pooled data have identified associations with other elements in the HLA complex, especially HLA-A and HLA-B. The most significant association is with HLA-B39, which confers high risk for T1DM in 3 different populations, makes up the majority of the signal from HLA-B, and is associated with a lower age of onset of the disease.

### Insulin Gene Locus, IDDM2
The second locus found to be associated with risk of T1DM was labeled IDDM2 and has been localized to a region upstream of the insulin gene (i.e., 5′ of the insulin gene). It is estimated that this locus accounts for approximately 10% of the familial risk of T1DM. Susceptibility in this region has been primarily mapped to a variable number of tandem repeats approximately 500 bp upstream of the insulin gene. This highly polymorphic region consists of anywhere from 30 to several hundred repeats of a 14-15 bp unit sequence (ACAGGGCGTCTGGGG). A shorter number of repeats is associated with increased risk of T1DM.

### PTPN22 (Lymphoid Tyrosine Phosphatase)
A single-nucleotide polymorphism in the PTPN22 gene on chromosome 1p13 that encodes lymphoid tyrosine phosphatase correlates strongly with the incidence of T1DM in 2 independent populations. This gene has an association with several other autoimmune diseases such as rheumatoid arthritis, systemic lupus erythematosus, vitiligo, and Graves disease.

### Cytotoxic T Lymphocyte Antigen 4
The cytotoxic T lymphocyte antigen 4 (CTLA-4) gene is located on chromosome 2q33 and is associated with T1DM as well as Graves disease, Hashimoto thyroiditis, celiac disease, and systemic lupus erythematosus. This gene is a negative regulator of T-cell activation.

### Interleukin-2 Receptor
Single-nucleotide polymorphisms in or near the gene for the IL-2 receptor have been found to have an association with T1DM risk. Studies with IL-2 in T1DM to date have not been successful in halting progression.

### Interleukin-1 Receptor
IL-1 receptor activation and chemokines involved in monocyte/macrophage and neutrophil chemotaxis have been also identified as critical steps in nitric oxide–induced islet necrosis and subsequent apoptosis. Indeed, inhibition of the activation of IL-1β–dependent inflammatory pathways by an IL-1 receptor antagonist in cultured rat islets exposed to nitric oxide prevented necrosis and apoptosis.
supporting evaluation in human islets in vitro and potentially as a posttransplantation therapy. IL-1 blockade in patients with T1DM has not halted progression.

**Interferon-Induced Helicase**

Another gene identified as having a modest effect on the risk of T1DM is the interferon-induced helicase (IFIH1) gene. Significant association exists with T1DM as well as Graves disease and multiple sclerosis. This gene is thought to play a role in protecting the host from viral infections and given the specificity of different helicases for different RNA viruses, it is possible that knowledge of this gene locus will help to narrow down the list of viral pathogens that may have a role in T1DM.

**CYP27B1**

Cytochrome P450, subfamily 27, polypeptide 1 gene encodes vitamin D 1α-hydroxylase. Because of the known role of vitamin D in immune regulation and because of epidemiologic evidence that vitamin D may play a role in T1DM, this gene was examined as a candidate gene and 2 single-nucleotide polymorphisms were found to be associated.

**ENVIRONMENTAL FACTORS**

That 50% or so of monozygotic twins are discordant for T1DM, the variation seen in urban and rural areas populated by the same ethnic group, the change in incidence that occurs with migration, the increase in incidence that has been seen in almost all populations in the last few decades, and the occurrence of seasonality all provide evidence that environmental factors also play a significant role in the causation of T1DM.

**Viral Infections**

It is possible that various viruses do play a role in the pathogenesis of T1DM, but no single virus, and no single pathogenic mechanism, stands out in the environmental etiology of T1DM. Instead, a variety of viruses and mechanisms may contribute to the development of diabetes in genetically susceptible hosts. Invoked mechanisms involved direct infection of β-cells by viruses resulting in lysis and release of self-antigens, direct viral infection of antigen-presenting cells causing increased expression of cytokines, and “molecular mimicry,” the notion that viral antigens exhibit homology to self-epitopes.

**Congenital Rubella Syndrome**

The clearest evidence of a role for viral infection in human T1DM is seen in congenital rubella syndrome. Prenatal infection with rubella is associated with β-cell autoimmunity in up to 70%, with development of T1DM in up to 40% of infected children. The time lag between infection and development of diabetes may be as high as 20 yr. T1DM after congenital rubella is more likely in patients that carry the higher-risk genotypes. Interestingly, there appears to be no increase in risk of diabetes when rubella infection develops after birth or when live-virus rubella immunization is used.

**Enteroviruses**

Studies show an increase in evidence of enteroviral infection in patients with T1DM and an increased prevalence of enteroviral RNA in prenatal blood samples from children who subsequently develop T1DM. In addition, there are case reports of association between enteroviral infection and subsequent T1DM. But the true significance of these infections remains unknown at this time.

**Mumps Virus**

It has been variably observed that mumps infection leads to the development of β-cell autoimmunity with high frequency and to T1DM in some cases. Although mumps may play a role in some cases of diabetes, the fact that T1DM diabetes incidence has increased steadily in several countries after universal mumps vaccination was introduced and that the incidence is extremely low in several populations where mumps is still prevalent indicates that mumps alone is not a major causal factor in diabetes.

**The Hygiene Hypothesis: Possible Protective Role of Infections**

Although some viral infections may increase the risk of T1DM, infectious agents may also play a protective role against diabetes. The hygiene hypothesis states that T1DM is a disease of industrialized countries, where the observation that there are fewer infections implies that the immune system is less well trained for its main task, namely host defense. Some call this theory the “microbial deprivation hypothesis.” The hygiene hypothesis states that lack of exposure to childhood infections may increase an individual’s chances of developing autoimmune diseases, including T1DM. Rates of T1DM and other autoimmune disorders are generally lower in underdeveloped nations with a high prevalence of childhood infections and tend to increase as these countries become more developed. The incidence of T1DM differs almost 6-fold between Russian Karelia and Finland, even though both are populated by a genetically related population and are adjacent to each other and at the same latitude. The incidence of autoimmunity in the 2 populations varies inversely with immunoglobulin (Ig) E antibody levels, and IgE is involved in the response to parasitic infestation. All these observations indicate that decreased exposure to certain parasites and other microbes in early childhood may lead to an increased risk of autoimmunity in later life, including autoimmune diabetes. On the other hand, retrospective case-control studies have been equivocal at best and direct evidence of protection by childhood infections is still lacking.

**Diet**

Breastfeeding may lower the risk of T1DM, either directly or by delaying exposure to cow’s milk protein. Early introduction of cow’s milk protein and early exposure to gluten are implicated in the development of autoimmunity and it has been suggested that this is a result of the “leakiness” of the immature gut to protein antigens. Implicated antigens include β-lactoglobulin, a major lipocalin protein in bovine milk, which is homologous to the human protein glycodelin (PP14), a T-cell modulator. Other studies focused on bovine serum albumin as the initiating antigen, but the data are contradictory and not yet conclusive. In addition, milk and milk products are also indicators of the level of contamination of persistent organic pollutants, polychlorinated biphenyls, dioxin, and others. One large study in infants who are at high risk for T1DM did not demonstrate a reduced incidence of diabetes-associated autoantibodies when fed an extensively hydrolyzed vs cow milk–based formula. A smaller study demonstrated a reduced incidence of autoantibody production in infants fed a whey-based formula that was free of bovine insulin. Additional studies are underway and should be available in 2017.

Other dietary factors that have been suggested at various times as playing a role in diabetes risk include omega-3 fatty acids, vitamin D, ascorbic acid, zinc, and vitamin E. Vitamin D is biologically plausible (it has a role in immune regulation), deficiency is more common in northern countries like Finland, and there is some epidemiologic evidence that decreased vitamin D levels in pregnancy or early childhood may be associated with diabetes risk; but the evidence is not yet conclusive and it is hoped that ongoing studies like TEDDY (The Environmental Determinants of Diabetes in the Young) will help to resolve some of the uncertainties in this area.

**Psychologic Stress**

Several studies show an increased prevalence of stressful psychologic situations among children who subsequently developed T1DM. Whether these stresses only aggravate preexisting autoimmunity or whether they can actually trigger autoimmunity through epigenetic mechanisms remains unknown.

**PATHOGENESIS AND NATURAL HISTORY OF TYPE 1 DIABETES MELLITUS**

In T1DM, a genetically susceptible host develops autoimmunity against the host’s own β cells. What triggers this autoimmune response remains unclear at this time. In some (but not all) patients, this autoimmune process results in progressive destruction of β cells until a critical mass
of β cells is lost and insulin deficiency develops. Insulin deficiency, in turn, leads to the onset of clinical signs and symptoms of T1DM. At the time of diagnosis, some viable β cells are still present and these may produce enough insulin to lead to a partial remission of the disease (honeymoon period) but over time, almost all β cells are destroyed and the patient becomes totally dependent on exogenous insulin for survival (Fig. 589-3). Over time, some of these patients develop secondary complications of diabetes that appear to be related to how well-controlled the diabetes has been. Thus, the natural history of T1DM involves some or all of the following stages:

1. Initiation of autoimmunity
2. Preclinical autoimmunity with progressive loss of β-cell function
3. Onset of clinical disease
4. Transient remission
5. Established disease
6. Development of complications

**Initiation of Autoimmunity**

Genetic susceptibility to T1DM is determined by several genes (see “Genetics” below), with the largest contribution coming from variants in the HLA system. But it is important to keep in mind that even with the highest-risk haplotypes, most carriers will not develop T1DM. Even in monozygotic twins, the concordance is 30-65%. The observed rise in incidence of T1DM within an essentially genetically stable patient population implies that something has accordingly changed in the environment or the way children are raised. A number of factors, including prenatal influences, diet in infancy, viral infections, lack of exposure to certain infections, even psychologic stress, are implicated in the pathogenesis of T1DM, but their exact role and the mechanism by which they trigger or aggravate autoimmunity remains uncertain (Fig. 589-4). What is clear is that markers of autoimmunity are much more prevalent than clinical T1DM, indicating that initiation of autoimmunity is a necessary but not a sufficient condition for T1DM. Whatever the triggering factor, it seems that in most cases of T1DM that are diagnosed in childhood, the onset of autoimmunity occurs very early in life. In a majority of the children diagnosed before age 10 yr, the first signs of autoimmunity appear before age 2 yr. Development of autoimmunity is associated with the appearance of several autoantibodies. IAAs are usually the first to appear in young children, followed by glutamic acid decarboxylase 65 kDa, and later by tyrosine phosphatase insulinoma–associated 2 and zinc transporter 8 antibodies. The earliest antibodies are predominantly of the IgG subclass. Not only is there “spreading” of autoimmunity to more antigens (IAA, and...
then glutamic acid decarboxylase 65 and insulinoma-associated 2 and zinc transporter 8) but there is also epitope spreading within 1 antigen. Initial glutamic acid decarboxylase 65 antibodies tend to be against the middle region or the carboxyl-terminal region, whereas aminoterminal antibodies usually appear later and are less common in children.

**Preclinical Autoimmunity with Progressive Loss of β-Cell Function**

In some, but not all, patients, the appearance of autoimmunity is followed by progressive destruction of β cells. Antibodies are a marker for the presence of autoimmunity, but the actual damage to the β cells is primarily T-cell mediated (Fig. 589-5). Histologic analysis of the pancreas from patients with recent-onset T1DM reveals insulitis, with an infiltration of the islets of Langerhans by mononuclear cells, including T and B lymphocytes, monocytes/macrophages, and natural killer cells. In the nonobese diabetic mouse, a similar cellular infiltrate is followed by linear loss of β cells until they completely disappear. But it appears that the process in human T1DM is not necessarily linear and there may be an undulating downhill course, with remissions and relapses, in the development of T1DM.

**Role of Autoantibodies**

Even though T1DM does not occur as a direct consequence of autoantibody formation, the risk of developing clinical disease increases dramatically with an increase in the number of antibodies; only 30% of children with 1 antibody will progress to diabetes, but this risk increases to 70% when 2 antibodies are present and 90% when 3 are present.

The risk of progression also varies with the intensity of the antibody response and those with higher antibody titers are more likely to progress to clinical disease. Another factor that appears to influence progression of β-cell damage is the age at which autoimmunity develops; children in whom IAAs appeared within the 1st 2 yr of life rapidly developed anti–islet cell antibodies and progressed to diabetes more frequently than children in whom the first antibodies appeared between ages 5 and 8 yr.

**Role of Genetics in Disease Progression**

Genetics plays a role in progression to clinical disease. In a large study of healthy children, the appearance of single antibodies is relatively common and usually transient, and does not correlate with the presence of high-risk HLA alleles, but those carrying high-risk HLA alleles are more likely to develop multiple antibodies and progress to disease. Similarly, the appearance of antibodies is more likely to predict diabetes in those with a family history of diabetes vs those with no family history of T1DM. Thus, it may be the case that environmental factors can induce transient autoimmunity in many children, but those with genetic susceptibility are more likely to see progression of autoimmunity and eventual development of diabetes.

**Role of Environmental Factors**

In addition to genetic factors, environmental factors may also act as accelerators of T1DM after the initial appearance of autoimmunity. This is evident from the fact that the incidence of T1DM can vary several-fold between populations that have the same prevalence of autoimmunity. For instance, the incidence of T1DM in Finland is almost 4-fold higher than in Lithuania, but the incidence of autoimmunity is similar in both countries.

The fact that all children with evidence of autoimmunity and of autoreactive T cells do not progress to diabetes indicates that there are “checkpoints” at which the autoimmune process can be halted or

---

**Figure 589-5** Schematic of the autoimmune response against pancreatic β cells. An insult to the pancreas leads to the release of β-cell antigens (GAD65), which are taken up by antigen-presenting cells (APCs) and the epitopes presented to the CD4 T cells. Type and stage of activation of APCs as well as the cytokine environment, in which the CD4 T-cell priming takes place, dictate the differentiation of autoreactive T cells toward diabetogenic T-helper type 1 (Th1) cells, T-helper type 2 (Th2) cells, or antigen-specific regulatory T cells. A predominant Th1 autoimmune response results in the recruitment and differentiation of cytotoxic CD8 cells, which attack the pancreatic β cells, leading to a massive release of β-cell antigens (Ag), epitope spreading, and destruction of the pancreatic islets. B, B lymphocyte; CTL, cytotoxic cell; DC, dendritic cell; IL, interleukin; INFγ, interferon-γ; M, macrophage; TGF-β, tumor growth factor β. (Adapted from Casares S, Brumeanu TD: Insights into the pathogenesis of T1DM: a hint for novel immunospecific therapies, Curr Mol Med 1:357–378, 2001.)
reversed before it progresses to full-blown diabetes. This has raised the possibility of preventing T1DM by intervening in the preclinical stage.

Onset of Clinical Disease
Patients with progressive β-cell destruction will eventually present with clinical T1DM. It was thought that 90% of the total β-cell mass is destroyed by the time clinical disease develops, but later studies have revealed that this is not always the case. It now appears that β-cell destruction is more rapid and more complete in younger children, while in older children and adults the proportion of surviving β cells is greater (10–20% in autopsy specimens) and some β cells (about 1% of the normal mass) survive up to 30 yr after the onset of diabetes. As autopsies are usually done on patients who died of diabetic ketoacidosis, these figures may underestimate the actual β-cell mass present at diagnosis. Functional studies indicate that up to 40% of the insulin secretory capacity may be preserved in adults at the time of presentation of T1DM. Ultrasensitive assays indicate that C-peptide production is measurable decades after onset of T1DM. The fact that newly diagnosed diabetic individuals may still have a significant surviving β-cell mass is important because it raises the possibility of secondary prevention of T1DM. Similarly, the existence of viable β cells years or decades after initial presentation indicates that even patients with long-standing diabetes may be able to exhibit some recovery of β-cell function if the autoimmune destructive process can be halted and islet cell regeneration occurs.

PREDICTION AND PREVENTION
Autoimmunity precedes clinical T1DM, and indicators of maturing autoimmune responses may be useful markers for disease prediction. Individuals at risk for T1DM can be identified by a combination of genetic, immunologic, and metabolic markers. The most informative genetic locus, HLA class II, confers about half of the total genetic risk but has a low positive predictive value (PPV) when used in the general population. Autoantibodies provide a practical readout of β-cell autoimmunity, are easily sampled in venous blood, and have become the mainstay of T1DM prediction efforts. In the 1st-degree relatives of patients with T1DM, the number of positive autoantibodies can help estimate the risk of developing T1DM: low risk (single autoantibodies: PPV of 2-6%), moderate risk (2 autoantibodies: PPV of 21-40%), and high risk (>2 autoantibodies: PPV of 59-80%) over a 5 yr period. In children carrying the T1DM highest-risk genotype (HLA-

Primary Prevention of Type 1 Diabetes Mellitus
A safe, effective, inexpensive, and easily administered intervention could theoretically be targeted at all newborns, but no such universally effective intervention is yet available. Delaying the introduction of cow's milk protein, delaying introduction of cereals, and increasing the duration of breastfeeding are all potentially beneficial but of unproven value.

In high-risk populations (relatives of individuals with T1DM, especially those with high-risk genotypes), it is feasible to test more targeted interventions. Parenteral insulin and nasal insulin proved similarly ineffective in preventing diabetes, but oral insulin appeared to delay the incidence of diabetes in only some of autoantibody-positive but still prediabetic patients. In the approach to the newly diagnosed patient with T1DM, antigen-specific immunotherapy trials studying the effect of glutamic acid decarboxylase formulated in aluminum hydroxide, IL-1β inhibition, or intranasal insulin have been negative, and anti-CD3 antibodies have been inconclusive.

Secondary Prevention
Immunosuppressants like cyclosporine have been tested after the onset of T1DM, but while they may prolong the honeymoon period, they are associated with significant side effects and are only effective as long as they are being administered, so their use for this purpose has been abandoned.

The possibility of using glucagon-like peptide (GLP)-1 agonists (e.g., exenatide) alone or in combination with immunomodulatory therapies is also being explored as these agents are capable of increasing β-cell mass in animals.

PATHOPHYSIOLOGY
Insulin performs a critical role in the storage and retrieval of cellular fuel. Its secretion in response to feeding is exquisitely modulated by the interplay of neural, hormonal, and substrate-related mechanisms to permit controlled disposition of ingested foodstuff as energy for immediate or future use. Insulin levels must be lowered to then mobilize stored energy during the fasted state. Thus, in normal metabolism, there are regular swings between the postprandial, high-insulin anabolic state and the fasted, low-insulin catabolic state that affect liver, muscle, and adipose tissue (Table 589-3). T1DM is a progressive low-insulin catabolic state in which feeding does not reverse, but rather exaggerates, these catabolic processes. With moderate insulinopenia, glucose utilization by muscle and fat decreases and postprandial hyperglycemia appears. At even lower insulin levels, the liver produces excessive glucose via glycogenolysis and gluconeogenesis, and fasting hyperglycemia begins. Hyperglycemia produces an osmotic diuresis (glycosuria) when the renal threshold is exceeded (180 mg/dL; 10 mmol/L). The resulting loss of calories and electrolytes, as well as the worsening dehydration, produces a physiologic stress with hypersecretion of stress hormones (epinephrine, cortisol, growth hormone, and glucagon). These hormones, in turn, contribute to the metabolic decompensation by further impairing insulin secretion (epinephrine), by antagonizing its action (epinephrine, cortisol, growth hormone), and by promoting glycogenolysis, gluconeogenesis, lipolysis, and ketogenesis (glucagon, epinephrine, growth hormone, and cortisol) while decreasing glucose utilization and glucose clearance (epinephrine, growth hormone, cortisol).

*Insulin is considered to be the major factor governing these metabolic processes. Diabetes mellitus may be viewed as a permanent low-insulin state that, untreated, results in exaggerated fasting.
The combination of insulin deficiency and elevated plasma values of the counterregulatory hormones is also responsible for accelerated lipolysis and impaired lipid synthesis, with resulting increased plasma concentrations of total lipids, cholesterol, triglycerides, and free fatty acids. The hormonal interplay of insulin deficiency and glucagon excess shunts the free fatty acids into ketone body formation; the rate of formation of these ketone bodies, principally $\beta$-hydroxybutyrate and acetoacetate, exceeds the capacity for peripheral utilization and renal excretion. Accumulation of these keto acids results in metabolic acidosis (diabetic ketoacidosis [DKA]) and compensatory rapid deep breathing in an attempt to excrete excess CO$_2$ (Kussmaul respiration). Acetone, formed by nonenzymatic conversion of acetoacetate, is responsible for the characteristic fruity odor of the breath. Ketones are excreted in the urine in association with cations and thus further increase losses of water and electrolyte and bicarbonate regenerating ability. With progressive dehydration, acidosis, hyperosmolality, and diminished cerebral oxygen utilization, consciousness becomes impaired, and the patient ultimately becomes comatose.

**CLINICAL MANIFESTATIONS**

In diabetes the decreasing $\beta$-cell mass with worsening insulinoopenia, progressive hyperglycemia, and eventual ketoacidosis all imply that symptoms steadily increase, from early intermittent polyuria to DKA and coma, over weeks usually, rather than months. Initially, when only insulin reserve is limited, occasional postprandial hyperglycemia occurs. When the serum glucose increases above the renal threshold, intermittent polyuria or nocturia begins. With further $\beta$-cell loss, chronic hyperglycemia causes a more persistent diuresis, often with nocturnal enuresis, and polydipsia becomes more apparent. Female patients may develop menial vaginitis from the chronic glycosuria. Calories are lost in the urine (glycosuria), triggering a compensatory hyperphagia. If this hyperphagia does not keep pace with the glycosuria, loss of body fat ensues, with clinical weight loss and diminished subcutaneous fat stores. An average, healthy 10 yr old child consumes approximately 50% of 2,000 daily calories as carbohydrate. As that child becomes diabetic, daily losses of water and glucose may be 5 L and 250 g, respectively, representing 1,000 calories, or 50%, of the average daily caloric intake. Despite the child's compensatory increased intake of food, the body starves because unused calories are lost in the urine.

When extremely low insulin levels are reached, ketoacids accumulate. At this point, the child quickly deteriorates. Ketoacids produce abdominal discomfort or true pain, nausea, and emesis, preventing oral replacement of urinary water losses. Dehydration accelerates, causing weakness or orthostasis—but polyuria persists. As in any hyperosmotic state, the degree of dehydration may be clinically underestimated because intravascular volume is conserved at the expense of intracellular volume. Ketoacidosis exacerbates prior symptoms and leads to Kussmaul respirations (deep, heavy, nonlabored rapid breathing), fruity breath odor (acetone), prolonged corrected Q-T interval, diminished neurocognitive function, and possible coma. Approximately 20-40% of children with new-onset diabetes progress to DKA before diagnosis.

This entire progression happens much more quickly (over a few weeks) in younger children, owing to either more aggressive autoimmune destruction of $\beta$ cells and/or to lower $\beta$-cell mass compared to older subjects. In infants, most of the weight loss is acute water loss because they will not have had prolonged urinary loss of calories from glycosuria, and there will be an increased incidence of DKA at diagnosis. In adolescents, the course is usually more prolonged (over a few months), and most of the weight loss represents fat loss from prolonged starvation. Additional weight loss from acute dehydration may occur just before diagnosis. In any child, the progression of symptoms may be accelerated by the stress of an intercurrent illness or trauma, when counterregulatory (stress) hormones overwhelm the limited insulin secretory capacity.

**DIAGNOSIS**

The diagnosis of T1DM is usually straightforward (see Table 589-2). Although most symptoms are nonspecific, the most important clue is an inappropriate polyuria in any child with dehydration, poor weight gain, or “the flu.” Hyperglycemia, glycosuria, and ketonuria can be determined quickly. Nonfasting blood glucose greater than 200 mg/dL (11.1 mmol/L) with typical symptoms is diagnostic with or without ketonuria. In the obese child, T2DM must be considered (see "Type 2 Diabetes Mellitus" below). Once hyperglycemia is confirmed, it is prudent to determine whether DKA is present (especially if ketonuria is found) and to evaluate electrolyte abnormalities—even if signs of dehydration are minimal. A baseline hemoglobin A$_1c$ ($\mathrm{HbA}_1c$) will be confirmatory and allows an estimate of the duration of hyperglycemia and provides an initial value by which to compare the effectiveness of subsequent therapy. Falsely low HbA$_1c$ levels are noted in hemolytic anemias, pure red cell aplasia, blood transfusions, and anemias associated with hemorrhage, cirrhosis, myelodysplasias, or renal disease treated with erthropoietin.

In the nonobese child, testing for autoimmunity to $\beta$ cells is not commonly necessary. Other autoimmunities associated with T1DM should be sought, including celiac disease (by tissue transglutaminase IgA and total IgA) and thyroiditis (by antithyroid peroxidase and antithyroglobulin antibodies). Fifteen to 30% of subjects with T1DM have elevated thyroid-stimulating hormone (TSH) and antithyroid antibodies and close to 5-10% have evidence for celiac disease. These diseases share common genes and likely the same interplay between environmental and immunologic factors. Because significant physiologic distress can disrupt the pituitary–thyroid axis, free thyroxine and TSH levels should be checked after the child is stable for a few weeks.

Rarely, a child has transient hyperglycemia with glycosuria while under substantial physical stress. This usually resolves permanently during recovery from the stressors. Stress-produced hyperglycemia can reflect a limited insulin reserve temporarily revealed by counterregulatory hormones. A child with temporary hyperglycemia should therefore be monitored for the development of symptoms of persistent hyperglycemia and tested if such symptoms occur. Formal testing in a child who remains clinically asymptomatic is not necessary; if there is concern for T1DM or T2DM a hemoglobin A$_1c$ may be of value.

Routine screening procedures, such as postprandial determinations of blood glucose or screening oral glucose tolerance tests have yielded low detection rates in healthy, asymptomatic children, even among those considered at risk, such as siblings of diabetic children. According, such screening procedures are not recommended in children.

**Diabetic Ketoacidosis**

DKA is the end result of the metabolic abnormalities resulting from a severe deficiency of insulin or insulin effectiveness. The latter occurs during stress as counterregulatory hormones block insulin action. DKA occurs in 20-40% of children with new-onset diabetes and in children with known diabetes who omit insulin doses or who do not successfully manage an intercurrent illness. DKA may be arbitrarily classified as mild, moderate, or severe (Table 589-4), and the range of symptoms depends on the depth of ketoacidosis. There is a large amount of ketonuria, an increased ion gap, a decreased serum bicarbonate (or total CO$_2$) and pH, and an elevated effective serum osmolality, indicating hypotonic dehydration.

**TREATMENT**

Therapy is tailored to the degree of insulinoopenia at presentation. Most children with new diabetes have mild to moderate symptoms, have minimal dehydration with no history of emesis, and have not progressed to ketoacidosis. Once DKA has resolved in the newly diagnosed child, therapy is transitioned to that described for children with nonketotic onset. Children with previously diagnosed diabetes who develop DKA are usually transitioned to their previous insulin regimen.

**NEW-ONSET DIABETES WITHOUT KETOACIDOSIS**

Excellent diabetes control involves many goals: to maintain a balance between tight glucose control and avoiding hypoglycemia, to eliminate polyuria and nocturia, to prevent ketoacidosis, and to permit normal growth and development with minimal effect on lifestyle. Therapy
encompasses initiation and adjustment of insulin, extensive teaching of the child and caretakers, and reestablishment of the life routines. Each aspect should be addressed early in the overall care.

**Insulin Therapy**

Several factors influence the initial daily insulin dose per kilogram of body weight. The dose is usually higher in pubertal children. It is also higher in those who are in DKA at the time of presentation. Table 589-5 shows the recommended starting total daily dose (units/kg/day) of insulin in children.

The optimal insulin dose can only be determined empirically, with frequent self-monitored blood glucose levels and insulin adjustment by the diabetes team. Many children with new-onset diabetes have some residual β-cell function (the honeymoon period), which is associated with reduced exogenous insulin needs shortly after starting on treatment. Residual β-cell function usually fades within a few months and is reflected as a steady increase in insulin requirements and wider glucose excursions.

The initial insulin schedule should be directed toward the optimal degree of glucose control in an attempt to duplicate the activity of the β cell. There are inherent limits to our ability to mimic the β cell. Exogenous insulin does not have a first pass to the liver, whereas 50% of pancreatic portal insulin is taken up by the liver, a key organ for the disposal of glucose; absorption of an exogenous dose continues despite hypoglycemia, whereas endogenous insulin release ceases and serum levels quickly lower with a normally rapid clearance. The absorption rate from an injection varies by injection site and patient activity level, whereas endogenous insulin is secreted directly into the portal circulation. Despite these fundamental physiologic differences, acceptable glucose control can be obtained with insulin analogs used in a basal-bolus regimen, that is, with slow-onset, long-duration background insulation and Ultralente injections with variable absorption characteristics and overlapping durations.

All preanalog insulins form hexamers, which must dissociate into monomers subcutaneously before being absorbed into the circulation. Thus, a detectable effect for regular insulin is delayed by 30-60 min after injection. This, in turn, requires delaying the meal 30-60 min after the injection for optimal effect—a delay rarely attained in a busy child’s life. Regular insulin has a wide peak and a long tail for bolus insulin (Figs. 589-6 and 589-7). This profile limits postprandial glucose control, produces prolonged peaks with excessive hypoglycemic effects between meals, and increases the risk of nighttime hypoglycemia. These unwanted between-meal effects often necessitate “feeding the insulin” with snacks and limiting the overall degree of blood glucose control. Neutral protamine Hagedorn (NPH) and Lente insulins also have inherent limits because they do not create a peakless background insulin level (see Fig. 589-7C-E). This produces a significant hypoglycemic effect during the midrange of their duration. Thus, it is often difficult to predict their interaction with fast-acting insulins. When regular insulin is combined with NPH or Lente (see Fig. 589-7E), the composite insulin profile poorly mimics normal endogenous insulin secretion. Lente and Ultralente insulins have been discontinued and are no longer available.

Lispro and aspart, insulin analogs, are absorbed much quicker because they do not form hexamers. They provide discrete pulses with little if any overlap and short tail effect. This allows better control of postmeal glucose increase and reduces between-meal or nighttime hypoglycemia.

- **A** Shows the recommended starting total daily dose (units/kg/day) of insulin in children.
- **B** Two Ultralente injections given at breakfast and supper. Note overlap of profiles. **C** Composite curve showing approximate cumulative insulin effect for the 2 Ultralente injections. This composite view is much more useful to the patient, parents, and medical personnel because it shows important combined effects of multiple insulin injections with variable absorption characteristics and overlapping durations.
Glargine may be given every 12 hr in young children if a single daily dose of glargine does not produce complete 24 hr basal coverage. The basal insulin glargine should be 25-30% of the total dose in toddlers and 40-50% in older children. The remaining portion of the total daily dose is provided as bolus insulin that is dosed by both the carbohydrate content of the meal as well as the preprandial glucose value.

Hypoglycemia (see Fig. 589-7A). The long-acting analog glargine creates a much flatter 24 hr profile, making it easier to predict the combined effect of a rapid bolus (lispro or aspart) on top of the basal insulin, producing a more physiologic pattern of insulin effect (see Fig. 589-7A). Postprandial glucose elevations are better controlled, and between-meal and nighttime hypoglycemia are reduced.

Glargine may be given every 12 hr in young children if a single daily dose of glargine does not produce complete 24 hr basal coverage. The basal insulin glargine should be 25-30% of the total dose in toddlers and 40-50% in older children. The remaining portion of the total daily dose is provided as bolus insulin that is dosed by both the carbohydrate content of the meal as well as the preprandial glucose value.
Frequent blood glucose monitoring and insulin adjustment are necessary in the 1st weeks as the child returns to routine activities and adapts to a new nutritional schedule, and as the total daily insulin requirements are determined. The major physiologic limit to tight control is hypoglycemia. Use of insulin analogs moderates but does not eliminate this problem.

Some families may be unable to administer 4 daily injections. In these cases, a compromise may be needed. A 3 injection regimen combining NPH with a rapid analog bolus at breakfast, a rapid-acting analog bolus at supper, and glargine at bedtime may provide fair glucose control. Further compromise to a 2 injection regimen may occasionally be needed and frequently involves use of premix insulin (e.g., 70/30).

**Insulin Pump Therapy**

Continuous subcutaneous insulin infusion (CSII) via battery-powered pumps provides a closer approximation of normal plasma insulin profiles and increased flexibility regarding timing of meals and snacks compared with conventional insulin injection regimens. Insulin pump models can be programmed with a patient's personal insulin dose algorithms, including the insulin to carbohydrate ratio and the correction scale for premeal glucose levels. The patient can enter the patient's blood glucose level and the carbohydrate content of the meal, and the pump computer will calculate the proper insulin bolus dose. Although CSII frequently improves metabolic control, this may not always be the case. The degree of glycemic control is mainly dependent on how closely patients adhere to the principles of diabetes self-care, regardless of the type of intensive insulin regimen. One benefit of pump therapy may be a reduction in severe hypoglycemia and associated seizures. Randomized trials comparing multiple daily insulin regimens using glargine insulin and CSII in children with T1DM demonstrate similar metabolic control and frequency of hypoglycemic events.

**Continuous Glucose Monitoring Systems**

Subcutaneous glucose sensors that continuously measure interstitial fluid glucose levels are available and approved for use in children. The 1st generation of continuous glucose monitors provided blood glucose data only after downloading by the physician, and did not provide real-time feedback to the patient. This type of device did not appear to improve glycemic control in children, although there was some educational value in detecting patterns of blood glucose fluctuations and episodes of hypoglycemia during periods of sleep.

The newer generation of continuous monitors report blood glucose levels to the patient in real time. Short-term studies indicate clinical benefits of these devices as compared to conventional methods of blood glucose monitoring, when used by motivated and well-informed patients. These devices do not directly control insulin administration but provide glucose readings to permit finer control of insulin administration by patients and families. To avoid hypoglycemia the glucose sensor sounds an alarm; many episodes of hypoglycemia occur at night and unfortunately the parent may sleep through the alarm. Studies are currently evaluating the efficacy of a fully automated closed-loop system of insulin delivery based on continuous glucose sensing, sometimes mistakenly known as an “artificial pancreas” (Fig. 589-8). Some automated glycemic systems employ a bihormonal approach (insulin, glucagon) or have an automated insulin suspension program to ensure normal glycemia while avoiding hypoglycemia. The latter hypoglycemia threshold insulin suspension feature greatly reduces the incidence of hypoglycemia, especially at night. The FDA has approved an insulin pump in combination with a continuous glucose monitoring system that will stop insulin delivery when interstitial glucose levels fall below a predetermined level.

**Amylin-Based Adjunct Therapy**

Pramlintide acetate, a synthetic analog of amylin, may be of therapeutic value combined with insulin therapy. In adolescents it has been shown to decrease postprandial hyperglycemia, insulin dosage, gastric emptying, and HbA1c levels. It is given as a subcutaneous dose before meals.

**Basic and Advanced Diabetes Education**

Therapy consists not only of initiation and adjustment of insulin dose but also of education of the patient and family. Teaching is most efficiently provided by experienced diabetes educators and nutritionists.
In the acute phase, the family must learn the “basics,” which includes monitoring the child’s blood glucose and urine and/or blood ketones, preparing and injecting the correct insulin dose subcutaneously at the proper time, recognizing and treating low blood glucose reactions, and having a basic meal plan. Most families are trying to adjust psychologically to the new diagnosis of diabetes in their child and thus have a limited ability to retain new information. Written materials covering these basic topics help the family during the first few days.

Children and their families are also required to complete advanced self-management classes in order to facilitate implementation of flexible insulin management. These educational classes will help patients and their families acquire skills for managing diabetes during athletic activities and sick days.

Ketoacidosis
Severe insulinopenia (or lack of effective insulin action) results in a physiologic cascade of events in 3 general pathways:
1. Excessive glucose production coupled with reduced glucose utilization raises serum glucose. This produces an osmotic diuresis, with loss of fluid and electrolytes, dehydration, and activation of the renin–angiotensin–aldosterone axis with accelerated potassium loss. If glucose elevation and dehydration are severe and persist for several hours, the risk of cerebral edema increases.
2. Increased catabolic processes result in cellular losses of sodium, potassium, and phosphate.
3. Increased release of free fatty acids from peripheral fat stores supplies substrate for hepatic ketoacid production. When ketoads accumulate, buffer systems are depleted and a metabolic acidosis ensues. Therapy must address both the initiating event in this cascade (insulinopenia) and the subsequent physiologic disruptions.

Reversal of DKA is associated with inherent risks that include hyperglycemia, hypokalemia, and cerebral edema. Any protocol must be used with caution and close monitoring of the patient. Adjustments based on sound medical judgment may be necessary for any given level of DKA (Table 589-6).

Hyperglycemia and Dehydration
Insulin must be given at the beginning of therapy to accelerate movement of glucose into cells, to subdue hepatic glucose production, and to halt the movement of fatty acids from the periphery to the liver. An initial insulin bolus does not speed recovery and may increase the risk of hypokalemia and hypoglycemia. Therefore, insulin infusion is typically begun without a bolus at a rate of 0.1 units/kg/hr. This approximates maximal insulin output in normal subjects during an oral glucose tolerance test. Rehydration also lowers glucose levels by improving renal perfusion and enhancing renal excretion. The combination of these therapies usually causes a rapid initial decline in serum glucose levels. Once glucose goes below 180 mg/dL (10 mmol/L), the osmotic diuresis stops and rehydration accelerates without further increase in the infusion rate.

Repair of hyperglycemia occurs well before correction of acidosis. Therefore, insulin is still needed to control fatty acid release and ketosis after normal glucose levels are reached. To continue the insulin infusion without causing hypoglycemia, glucose must be added to the infusion. We typically recommend that glucose be added as a 5% solution when the serum glucose has decreased <300 mg/dL and as a 10% solution when the serum glucose has decreased <200 mg/dL. The insulin infusion can also be lowered from the initial maximal rate if, despite the above outlined interventions, the serum glucose falls further.

Repair of fluid deficits must be tempered by the potential risk of cerebral edema. It is prudent to approach any child in any hyperosmotic state with cautious rehydration. The effective serum osmolality \( (\text{Eq}_{\text{serum}} = 2 \times [\text{Na}_{\text{uncorrected}}] + [\text{glucose}]) \) is an accurate index of tonicity of the body fluids, reflecting intracellular and extracellular hydration better than measured plasma osmolality. It is calculated with sodium and glucose in mmol/L. This value is usually elevated at the beginning of therapy and should steadily normalize. A rapid decline, or a slow decline to a subnormal range, may indicate an excess of free water entering the vascular space and an increasing risk of cerebral edema. Therefore, patients should not be allowed oral fluids until rehydration is well underway and significant electrolyte shifts are no longer likely. Limited ice chips may be given as a minimal oral intake. All fluid intake and output should be closely monitored.

Calculation of fluid deficits using clinical signs is difficult in children with DKA because intravascular volume is better maintained in the hypertonic state. For any degree of tachycardia, delayed capillary refill, decreased skin temperature, or orthostatic blood pressure change, the child with DKA will be more dehydrated than the child with a normotonic fluid deficit. The protocol in Table 589-6 corrects a deficit of 85 mL/kg (8.5% dehydration) for all patients in the 1st 24 hr. Children with mild DKA rehydrate earlier and can be switched to oral intake.

### Table 589-6: Diabetic Ketoacidosis Treatment Protocol

<table>
<thead>
<tr>
<th>TIME</th>
<th>THERAPY</th>
<th>COMMENTS</th>

</tr>
<tr>
<td>2nd hr</td>
<td>0.45% NaCl: plus continue insulin drip 20 mEq/L KPhos and 20 mEq/L KAc 5% glucose if blood sugar &gt;250 mg/dL (14 mmol/L)</td>
<td>IV rate = ( \frac{85 \text{ mL/kg + maintenance - bolus}}{23 \text{ hr}} ) If K &lt; 3 mEq/L, give 0.5-1.0 mEq/kg as oral K solution or increase IV K to 80 mEq/L</td>
</tr>
<tr>
<td>Variable</td>
<td>Oral intake with subcutaneous insulin</td>
<td>No emesis; CO2 ≥16 mEq/L; normal electrolytes</td>
</tr>
</tbody>
</table>

Note that the initial IV bolus is considered part of the total fluid allowed in the 1st 24 hr and is subtracted before calculating the IV rate. Maintenance (24 hr) = 100 mL/kg (for the first 10 kg) + 50 mL/kg (for the second 10 kg) + 25 mL/kg (for all remaining kg)

Sample calculation for a 30-kg child:

1st hr = 300 mL IV bolus 0.9% NaCl or LR

\[
2nd \text{ and subsequent hr} = \left( \frac{85 \text{ mL x 30} + 1750 \text{ mL} - 300 \text{ mL}}{23 \text{ hr}} \right) = \frac{175 \text{ mL}}{23 \text{ hr}}
\]

\[
(0.45\% \text{NaCl with 20 mEq/L Kphos and 20 mEq/L KAc})
\]

DKA, diabetic ketoacidosis; I/O, input and output (urine, emesis); K, potassium; KAc, potassium acetate; KPhos, potassium phosphate; LR, lactated Ringer solution; NaCl, sodium chloride; NPO, nothing by mouth.
whereas those with severe DKA and a greater volume deficit require 30-36 hr with this protocol. This more gradual rehydration of the child with severe DKA is an inherent safety feature. The initial intravenous bolus (20 mL/kg of glucose-free isotonic sodium salt solution such as Ringer lactate or 0.9% sodium chloride) for all patients ensures a quick volume expansion and may be repeated if clinical improvement is not quickly seen. This bolus is given as isotonic saline because the patient is inevitably hypotonic, keeping most of the initial infusion in the intravascular space. Subsequent fluid is hypotonic to repair the free water deficit, to allow intracellular rehydration, and to allow a more appropriate replacement of ongoing hypotonic urine losses.

The initial serum sodium is usually normal or low because of the osmolar dilution of hyperglycemia and the effect of an elevated sodium-free lipid fraction. An estimate of the reconstituted, or "true," sodium serum for any given glucose level above 100 mg/dL (5.6 mmol/L) is calculated as follows:

\[ [\text{Na}^+] + (1.6 \text{ mEq/L Na}^+ \text{ for every 100 mg/dL glucose in excess of 100}) \]

or

\[ [\text{Na}^+] + (1.6 \text{ mEq/L Na}^+ \text{ for every 5.6 mmol/L glucose in excess of 5.6}) \]

The sodium should increase by approximately 1.6 mEq/L for each 100 mg/dL decline in the glucose. The corrected sodium is usually normal or slightly elevated and indicates moderate hypernatremic dehydration. If the corrected value is greater than 150 mmol/L, severe hypernatremic dehydration may be present and may require slower fluid replacement. The sodium should steadily increase with therapy. Declining sodium may indicate excessive free water accumulation and increased risk of cerebral edema.

Catabolic Losses

Both the metabolic shift to a catabolic predominance and the acidosis move potassium and phosphate from the cell to the serum. The osmotic diuresis, the kaliuretic effect of the hyperaldosteronism, and the ketonuria then accelerate renal losses of potassium and phosphate. Sodium is also lost with the diuresis, but free water losses are greater than isotonic losses. With prolonged illness and severe DKA, total body losses can approach 10-13 mEq/kg of sodium, 5-6 mEq/kg of potassium, and 4-5 mEq/kg of phosphate. These losses continue for several hours during therapy until the catabolic state is reversed and the diuresis is controlled. For example, 50% of infused sodium may be lost in the urine during IV therapy. Even though the sodium deficit may be repaired within 24 hr, intracellular potassium and phosphate may not be completely restored for several days.

Although patients with DKA have a total body potassium deficit, the initial serum level is often normal or elevated. This is caused by the movement of potassium from the intracellular space to the serum, both as part of the ketoacid buffering process and as part of the catabolic shift. These effects are reversed with therapy, and potassium returns to the cell. Improved hydration increases renal blood flow, allowing for increased excretion of potassium in the elevated aldosterone state. The net effect is often a dramatic decline in serum potassium levels, especially in severe DKA, and can precipitate changes in cardiac conductivity, flattening of T waves, and prolongation of the QRS complex and can cause skeletal muscle weakness or ileus. The risk of myocardial dysfunction is increased with shock and acidosis. Potassium levels must be closely followed and electrocardiographic monitoring continued until DKA is substantially resolved. If needed, the parenteral potassium can be increased to 80 mEq/L or an oral supplement can be given if there is no emesis. Rarely, the IV insulin must be temporarily stopped.

It is unclear whether phosphate deficits contribute to symptoms of DKA such as generalized muscle weakness. In pediatric patients, a deficit has not been shown to compromise oxygen delivery via a deficiency of 2,3-diphosphoglycerate. Because the patient will receive an excess of chloride, which may aggravate acidosis, it is prudent to use potassium phosphate rather than potassium chloride as a potassium source. Potassium acetate is also used, because it provides an additional buffer.

Pancreatitis is occasionally seen with DKA, especially if prolonged abdominal distress is present; serum amylase may be elevated. If the serum lipase is not elevated, the amylase is likely nonspecific or salivary in origin. Serum creatinine adjusted for age may be falsely elevated owing to interference by ketones in the autoanalyzer methodology. An initial elevated value rarely indicates renal failure and should be rechecked when the child is less ketonemic. Blood urea nitrogen may be elevated with prerenal azotemia and should be rechecked as the child is rehydrated. Mildly elevated creatine or blood urea nitrogen is not a reason to withhold potassium therapy if good urinary output is present.

Keto Acid Accumulation

Low insulin infusion rates (0.02-0.05 units/kg/hr) are usually sufficient to stop peripheral release of fatty acids, thereby eliminating the flow of substrate for ketogenesis. Therefore, the initial infusion rate may be decreased if blood glucose levels go below 150 mg/dL (8 mmol/L) despite the addition of glucose to the infusion. Ketogenesis continues until fatty acid substrates already in the liver are depleted, but this production declines much more quickly without new substrate inflow. Bicarbonate buffers, regenerated by the distal renal tubule and by metabolism of ketone bodies, steadily repair the acidosis once ketoacid production is controlled. Bicarbonate therapy is rarely necessary and may even increase the risk of hypokalemia and cerebral edema.

There should be a steady increase in pH and serum bicarbonate as therapy progresses. Kussmaul respirations should abate and abdominal pain resolve. Persistent acidosis may indicate inadequate insulin or fluid therapy, infection, or rarely lactic acidosis. Urine ketones may be positive long after ketoacidosis has resolved because the nitroprusside reaction routinely used to measure urine ketones by dipstick measures only acetoacetate. During DKA, most excess ketones are β-hydroxybutyrate, which increases the normal ratio to acetoacetate from 3:1 to as high as 8:1. With resolution of the acidosis, β-hydroxybutyrate converts to acetoacetate, which is excreted into the urine and detected by the dipstick test. Therefore, persistent ketonuria may not accurately reflect the degree of clinical improvement and should not be relied on as an indicator of therapeutic failure.

All patients with DKA should be checked for initiating events that may have triggered the metabolic decompensation.

Diabetic Ketoacidosis Protocol

See Table 589-6.

Even though DKA can be of variable severity, a common approach to all cases simplifies the therapeutic regimen and can be safely used for most children. Fluids are best calculated based on weight, not body surface area (m²), because heights are rarely available for the acutely critically ill child. A standard water deficit (85 mL/kg) is assumed. This amount, when added to maintenance, yields approximately 4 L/m² for children of all sizes. Children with milder DKA recover in 10-20 hr (and need less total IV fluid before switching to oral intake), whereas those with more severe DKA require 30-36 hr with this protocol. Any child can be easily transitioned to oral intake and subcutaneous insulin when DKA has resolved (total CO₂ >15 mEq/L; pH >7.30; sodium stable between 135 and 145 mEq/L; no emesis). The first dose of short-acting subcutaneous insulin is given with a meal, and the insulin drip is discontinued approximately 30 min later.

A flow sheet is mandatory for accurate monitoring of changes in acidosis, electrolytes, fluid balance, and clinical status, especially if the patient is transferred from the emergency department to an inpatient setting with new caretakers. This flow sheet is best implemented by a central computer system, which allows for rapid update and wide availability of results, as well as rule-driven highlighting of critical values. A paper flow sheet suffices if it stays with the patient, is kept current, and is reviewed frequently by the physician. Any flow sheet should include columns for serial electrolytes, pH, glucose, and fluid balance. Blood testing should occur every 1-2 hr for children with severe DKA and every 3-4 hr for those with mild to moderate DKA.
Cerebral Edema

Cerebral edema complicating DKA remains the major cause of morbidity and mortality in children and adolescents with T1DM. However, its etiology remains unknown. A case-control study of DKA suggested that baseline acidosis and abnormalities of sodium, potassium, and blood urea nitrogen concentrations were important predictors of risk of cerebral edema. Early bolus administration of insulin and high volumes of fluid were also identified as risk factors. The incidence of cerebral edema in children with DKA has not changed over the past 15-20 yr, despite the widespread introduction of gradual rehydration protocols during this interval. Radiographic imaging is frequently unhelpful in making the diagnosis of cerebral edema. Consequently, each patient must be closely monitored. For all but the mildest cases, this includes frequent neurologic checks for any signs of increasing intracranial pressure, such as a change of consciousness, depressed respiration, worsening headache, bradycardia, apnea, pupillary changes, papilledema, posturing, and seizures. Mannitol must be readily available for use at the earliest sign of cerebral edema. The physician must also keep informed of the laboratory changes; hypokalemia or hypoglycemia can occur rapidly. Children with moderate to severe DKA have a higher overall risk and should be treated in an intensive care environment.

Nonketotic Hyperosmolar Coma

This syndrome is characterized by severe hyperglycemia (blood glucose >800 mg/dL), absence of or only slight ketosis, nonketotic acidosis, severe dehydration, depressed sensorium or frank coma, and various neurologic signs that may include grand mal seizures, hyperthermia, hemiparesis, and positive Babinski signs. Respirations are usually shallow, but coexistent metabolic (lactic) acidosis may be manifested by Kussmaul breathing. Serum osmolarity is commonly 350 mOsm/kg or greater. This condition is uncommon in children; among adults, mortality rates are high, possibly in part because of delays in recognition and institution of appropriate therapy. In children, there has been a high incidence of preexisting neurologic damage. Profound hyperglycemia may develop over a period of days and, initially, the obligatory osmotic polyuria and dehydration may be partially compensated for by increasing fluid intake. With progression of disease, thirst becomes impaired, possibly because of alteration of the hypothalamic thirst center by hyperosmolarity and, in some instances, because of a preexisting defect in the hypothalamic osmoregulating mechanism.

The low production of ketones is attributed mainly to the hyperosmolarity, which in vitro blunts the lipolytic effect of epinephrine and the antilipolytic effect of residual insulin; blunting of lipolysis by the therapeutic use of β-adrenergic blockers may contribute to the syndrome. Depression of consciousness is closely correlated with the degree of hyperosmolarity in this condition as well as in DKA. Hemocentration may also predispose to cerebral arterial and venous thromboses.

Treatment of nonketotic hyperosmolar coma is directed at rapid repletion of the vascular volume deficit and very slow correction of the hyperosmolar state. One-half isotonic saline (0.45% NaCl; some use normal saline) is administered at a rate estimated to replace 50% of the volume deficit in the 1st 12 hr, and the remainder is administered during the ensuing 24 hr. The rate of infusion and the saline concentration are titrated to result in a slow decline of serum osmolality. When the blood glucose concentration approaches 300 mg/dL, the hydrating fluid should be changed to 5% dextrose in 0.2 normal saline. Approximately 20 mEq/L of potassium chloride should be added to each of these fluids to prevent hypokalemia. Serum potassium and plasma glucose concentrations should be monitored at 2 hr intervals for the 1st 12 hr and at 4 hr intervals for the next 24 hr to permit appropriate adjustments of administered potassium and insulin.

Insulin can be given by continuous intravenous infusion beginning with the 2nd hr of fluid therapy. Blood glucose may decrease dramatically with fluid therapy alone. The IV insulin dosage should be 0.05 units/kg/hr rather than 0.1 units/kg/hr as advocated for patients with DKA.

Nutritional Management

Nutrition plays an essential role in the management of patients with T1DM. This is of critical importance during childhood and adolescence, when appropriate energy intake is required to meet the needs for energy expenditure, growth, and pubertal development. There are no special nutritional requirements for the diabetic child other than those for optimal growth and development. In outlining nutritional requirements for the child on the basis of age, sex, weight, and activity, food preferences, including cultural and ethnic ones, must be considered.

Total recommended caloric intake is based on size or surface area and can be obtained from standard tables (Tables 589-7 and 589-8). The caloric mixture should comprise approximately 55% carbohydrate, 30% fat, and 15% protein. Approximately 70% of the carbohydrate content should be derived from complex carbohydrates such as starch; intake of sucrose and highly refined sugars should be limited. Complex carbohydrates require prolonged digestion and absorption so that plasma glucose levels increase slowly, whereas glucose from refined sugars, including carbonated beverages, is rapidly absorbed and may cause wide swings in the metabolic pattern; carbonated beverages should be sugar free. Priority should be given to total calories and total carbohydrate consumed rather than its source. Carbohydrate counting has become a mainstay in the nutrition education and management of patients with DM. Patients and their families are provided with information regarding the carbohydrate contents of different foods and food label reading. This allows patients to adjust their insulin dosage to their mealtime carbohydrate intake. The use of carbohydrate counting and insulin to carbohydrate ratios and the use of fast-acting insulin analogs and long-acting basal insulin (detemir and glargine) provide many children with less rigid meal planning. Flexibility in the use of insulin in relation to carbohydrate content of food improves the quality of life.

Although in children there is concern about the potential cumulative effect of saccharin, available data do not support an association of moderate amounts with bladder cancer. Other nonnutritive sweeteners such as aspartame are used in a variety of products.

Diet with high fiber content are useful in improving control of blood glucose. Moderate amounts of sucrose consumed with fiber-rich foods such as whole-grain bread may have no more glycemic effect than their low-fiber, sugar-free equivalents.

The intake of fat is adjusted so that the polyunsaturated:saturated ratio is increased to approximately 1.2:1.0, in contrast to the estimated American average of 0.3:1.0. Dietary fats derived from animal sources are, therefore, reduced and replaced by polyunsaturated fats from vegetable sources. Substituting margarine for butter, vegetable oil for other fats, and substituting rice or other low-glycemic-index starches for higher-glycemic-index starches provide further benefits.

animal oils in cooking, and lean cuts of meat, poultry, and fish for fatty meats is advisable. The intake of cholesterol is also reduced by these measures and by limiting the number of egg yolks consumed. These simple measures reduce serum low-density lipoprotein cholesterol, a predisposing factor to atherosclerotic disease. Less than 10% of calories should be derived from saturated fats and up to 10% from polyunsaturated fats; the remaining fat-derived calories should be derived from monounsaturated fats. Table 589-8 summarizes current nutritional guidelines. Each child/family can and should select a diet based on personal taste with the help of the physician or dietitian (or both). Emphasis should be placed on regularity of food intake and on constancy of carbohydrate intake. Occasional excesses (“treats”) for birthdays and other parties are permissible and tolerated to not foster rebellion and steal in obtaining desired food. Cakes and even candies are permissible on special occasions as long as the food carbohydrate content is adjusted in the meal plan. Adjustments in meal planning must constantly be made to meet the needs as well as the desires of each child. A consistent eating pattern with appropriate supplements for exercise, the pubertal growth spurt, and pregnancy in an adolescent with diabetes is important for metabolic control.

**Monitoring**

Success in the daily management of the child with diabetes can be measured by the competence acquired by the family, and subsequently by the child, in assuming responsibility for daily self-care. Their initial and ongoing instruction in conjunction with their supervised experience can lead to a sense of confidence in making adjustments in insulin dosage for dietary deviations, for unusual physical activity, and even for some minor intercurrent illnesses. Such acceptance of responsibility should make them relatively independent of the physician for their ordinary care. The physician must maintain ongoing interest in supervision and shared responsibility with the family and the child.

Self-monitoring of blood glucose is an essential component of managing diabetes. Monitoring often also needs to include insulin dose, unusual physical activity, dietary changes, hypoglycemia, intercurrent illness, and other items that may influence the blood glucose. These items may be valuable in interpreting the self-monitoring of blood glucose record, prescribing appropriate adjustments in insulin doses, and teaching the family. If there are discrepancies in the self-monitoring of blood glucose and other measures of glycemic control (such as the HbA1c), the clinician should attempt to clarify the situation in a manner that does not undermine their mutual confidence.

Daily blood glucose monitoring has been markedly enhanced by the availability of strips impregnated with glucose oxidase that permit blood glucose measurement from a drop of blood. A portable calibrated reflectance meter can approximate the blood glucose concentration accurately. Many meters contain a memory “chip” enabling recall of each measurement, its average over a given interval, and the ability to display the pattern on a computer screen. Such information is a useful educational tool for verifying degree of control and modifying recommended regimens. A small, spring-loaded device that automates capillary bloodletting (lancing device) in a relatively painless fashion is commercially available. Parents and patients should be taught to use these devices and measure blood glucose at least 4 times daily—before breakfast, lunch, and supper, and at bedtime. When insulin therapy is initiated and when adjustments are made that may affect the overnight glucose levels, self-monitoring of blood glucose should also be performed at 12 midnight and 3 AM to detect nocturnal hypoglycemia. Ideally, the blood glucose concentration should range from approximately 80 mg/dL in the fasting state to 140 mg/dL after meals. In practice, however, a range is acceptable, based on age of the patient (Table 589-9). Blood glucose measurements that are consistently at or outside these limits, in the absence of an identifiable cause such as exercise or dietary indiscretion, are an indication for a change in the insulin dose. If the fasting blood glucose is high, the evening dose of long-acting insulin is increased by 10-15% and/or additional fast-acting insulin (lispro or aspart) coverage for bedtime snack may be considered. If the noon glucose level exceeds set limits, the morning fast-acting insulin (lispro or aspart) is increased by 10-15%. If the presupper glucose is high, the noon dose of fast-acting insulin is increased by 10-15%. If the presupper glucose is high, the presupper dose of fast-acting insulin is increased by 10-15%. Similarly, reductions in the insulin type and dose should be made if the corresponding blood glucose measurements are consistently below desirable limits.

A minimum of 4 daily blood glucose measurements should be performed. However, some children and adolescents may need to have more frequent blood glucose monitoring based on their level of physical activity and history of frequent hypoglycemic reactions. Families should be encouraged to become sufficiently knowledgeable about managing diabetes. They can maintain near-normal glycemia for prolonged periods by self-monitoring of blood glucose levels before and

### ADDITIONAL RECOMMENDATIONS

**Energy:** If using measured diet, reevaluate prescribed energy level at least every 3 mo.

**Protein:** High-protein intakes may contribute to diabetic nephropathy. Low intakes may reverse preclinical nephropathy. Therefore, 12-20% of energy is recommended; lower end of range is preferred. In guiding toward the end of the range, a staged approach is useful.

**Alcohol:** Safe use of moderate alcohol consumption should be taught as routine anticipatory guidance as early as junior high school.

**Snacks:** Snacks vary according to individual needs (generally 3 snacks per day for children; midafternoon and bedtime snacks for junior high children or teens).

**Alternative sweeteners:** Use a variety of sweeteners is suggested.

**Educational techniques:** No single technique is superior. Choice of educational method used should be based on patient needs. Knowledge of variety of techniques is important. Follow-up education and support are required.

**Eating disorders:** Best treatment is prevention. Unexplained poor control or severe hypoglycemia may indicate a potential eating disorder.

**Exercise:** Education is vital to prevent delayed or immediate hypoglycemia and to prevent worsened hyperglycemia and ketoosis.

---

2 hr after meals, and in conjunction with multiple daily injections of insulin, adjusted as necessary. 

A continuous glucose monitoring system (CGMS) records data obtained from a subcutaneous sensor every 5 min for up to 72 hr and provides the clinician with a continuous profile of tissue glucose levels. The interstitial glucose levels lag about 13 min behind the blood glucose values at any given level. The CGMS values tend to have a high correlation coefficient for blood glucose values ranging between 40 and 400 mg/dL. CGMS is minimally invasive and entails the placement of a small, subcutaneous catheter that can be easily worn by adults and children. The system provides information that allows the patient and healthcare team to adjust the insulin regimen and the nutrition plan to improve glycemic control. CGMS can be helpful in detecting asymptomatic nocturnal hypoglycemia as well as in lowering HbA1c values without increasing the risk for severe hypoglycemia. Although there are potential pitfalls in CGMS use, including suboptimal compliance, human error, incorrect technique, and sensor failure, the implementation of CGMS in ambulatory diabetes practice allows the clinician to diagnose abnormal glycemic patterns in a more precise manner.

**Real-Time Continuous Glucose Monitoring**

Real-time continuous glucose monitoring is a technology with the potential of transforming current concepts of glycemic control and optimal diabetes management. In addition to displaying real-time glucose data, newer generations of continuous glucose monitors also have alarms that can be set at below or above predetermined blood glucose thresholds. This safety feature can help parents of young children to recognize nocturnal hypoglycemia. In addition, continuous glucose monitoring shows the rate and direction of glucose change and alerts patients to trends that could lead to dangerous hypoglycemia or hyperglycemia. However, the use of continuous glucose monitoring without clinical decision-making algorithms and guidelines has not been proven to be very effective in improving glycemic control.

**Glycosylated Hemoglobin**

A reliable index of long-term glycemic control is provided by measurement of glycosylated hemoglobin, HbA1c. It is the fraction of hemoglobin to which glucose has been nonenzymatically attached in the bloodstream. The formation of HbA1c is a slow reaction that is dependent on the prevailing concentration of blood glucose; it continues reversibly throughout the red blood cell's life span of approximately 120 days. The higher the blood glucose concentration and the longer the red blood cell's exposure to it, the higher is the fraction of HbA1c, which is expressed as a percentage of total hemoglobin. Because a blood sample at any given time contains a mixture of red blood cells of varying ages, exposed for varying times to varying blood glucose concentrations, an HbA1c measurement reflects the average blood glucose concentration from the preceding 2-3 mo. When measured by standardized methods to remove labile forms, the fraction of HbA1c is not influenced by an isolated episode of hyperglycemia.

It is recommended that HbA1c measurements be obtained 3-4 times/yr to obtain a profile of long-term glycemic control. The lower the HbA1c level, the more likely it is that microvascular complications such as retinopathy and nephropathy will be less severe, delayed in appearance, or even avoided altogether. Depending on the method used for determination, HbA1c values may be spuriously elevated in thalassemia (or other conditions with elevated hemoglobin F) and spuriously lower in sickle cell disease (or other conditions with high red blood cell turnover). Although values of HbA1c may vary according to the method used for measurement, in individuals without diabetes, the HbA1c fraction is usually less than 6%; in individuals with diabetes, values of 6-7.5% represent good metabolic control, values of 7.6-9.9%, fair control, and values of 10% or higher, poor control. The target HbA1c of <7.5% is the same regardless of the patient's age (see Table 589-9).

**Exercise**

No form of exercise, including competitive sports, should be forbidden to the child with diabetes. A major complication of exercise in patients with diabetes is the presence of a hypoglycemic reaction during or within hours after exercise. If hypoglycemia does not occur with exercise, adjustments in diet or insulin are not necessary, and glucose regulation is likely to be improved through the increased utilization of glucose by muscles. The major contributing factor to hypoglycemia with exercise is an increased rate of absorption of insulin from its injection site. Higher insulin levels dampen hepatic glucose production so that it is inadequate to meet the increased glucose utilization of exercising muscle. Regular exercise also improves glucose regulation by increasing insulin receptor number. In patients who are in poor metabolic control, vigorous exercise may precipitate ketoacidosis because of the exercise-induced increase in the counterregulatory hormones.

**Benefits of Improved Glycemic Control**

The Diabetes Control and Complications Trial (DCCT) established conclusively the association between higher glucose levels and long-term microvascular complications. Intensive management produced dramatic reductions of retinopathy, nephropathy, and neuropathy by 47-76%. The data from the adolescent cohort demonstrated the same degree of improvement and the same relationship between the outcome measures of microvascular complications.

The beneficial effect of intensified treatment was determined by the degree of blood glucose normalization, independently of the type of intensified treatment used. Frequent blood glucose monitoring was considered an important factor in achieving better glycemic control for the intensively treated adolescents and adults. Patients who were intensively treated had individualized glucose targets, frequent adjustments based on ongoing capillary blood glucose monitoring, and a team approach that focused on the person with diabetes as the prime initiator of ambulatory care. Care was constantly adjusted toward reaching normal or near-normal glycemic goals while avoiding or minimizing severe episodes of hypoglycemia. Teaching emphasized a preventive approach to blood glucose fluctuations with constant readjustment to counterbalance any high or low blood glucose readings. Target blood glucose goals were adjusted upward if hypoglycemia could not be prevented.

Total duration of diabetes contributes to development and severity of complications. Nonetheless, many professionals have concerns

about applying the results of the DCCT to preschool-age children, who often have hypoglycemia unawareness with unique safety issues, and to prepubertal school-age children, who were not included in the DCCT. When the DCCT ended in 1993, researchers continued to study more than 90% of participants. The follow-up study, called Epidemiology of Diabetes Interventions and Complications (EDIC), was assessing the incidence and predictors of cardiovascular disease events such as heart attack, stroke, or needed heart surgery, as well as diabetic complications related to the eye, kidney, and nerves. The EDIC demonstrated that **intensive blood glucose control reduced risk** of any cardiovascular disease event by 42%. In addition, intensive therapy reduced risk of nonfatal heart attack, stroke, or death from cardiovascular causes by 57%.

### Current Intensive Insulin Replacement Regimens

The goal of physiologic insulin replacement for T1DM is accomplished with short-acting insulins that more closely mimic the sharp increase and short duration of pancreatic insulin secreted with nutrient intake. The rapid-acting insulin analog lispro has superior pharmacokinetic properties for the control of postprandial glucose. Improved postprandial glucose responses occur with twice-daily injections (conventional insulin), multiple daily insulin injections, or CSII. The use of lispro or aspart insulin reduces the frequency of between-meal hypoglycemic events, especially when it is carefully balanced with the carbohydrate content of meal.

The carbohydrate content of food does not influence glycemic control if premeal rapid-acting insulin (bolus) is adjusted to the carbohydrate content of the meal. Wide variations in carbohydrate intake do not modify long-acting (detemir or glargine) or basal insulin requirements. Insulin replacement strategies stress the importance of administering smaller doses of insulin throughout the day. This approach allows insulin doses to be changed as needed to correct hyperglycemia, supplement for additional anticipated carbohydrate intake, or subtract for exercise. Indeed, bolus-basal treatment with multiple injections is better adapted to the physiologic profiles of insulin and glucose and can therefore provide better glycemic control than the conventional 2-3 dose regimen. Age-adjusted and individualized insulin to carbohydrate ratios and insulin dosage adjustment algorithms have been developed to normalize elevated blood glucose levels and to compensate for alterations in carbohydrate intake. The use of flexible multiple daily injections and CSII in children with T1DM improves glycemic control without an increase in the incidence of severe hypoglycemia.

### Hypoglycemic Reactions

Hypoglycemia is the major limitation to tight control of glucose levels. Once injected, insulin absorption and action are independent of the glucose level, thus creating a unique risk of hypoglycemia from an unbalanced insulin effect. Insulin analogs may help reduce but cannot eliminate this risk. Most children with T1DM can expect mild hypoglycemia dia week, moderate hypoglycemia a few times each year, and severe hypoglycemia every few years. These episodes are usually not predictable, although exercise, delayed meals or snacks, and wide swings in glucose levels increase the risk. Infants and toddlers are at higher risk for hypoglycemia because they have more variable meals and activity levels, are unable to recognize early signs of hypoglycemia, and are limited in their ability to seek a source of oral glucose to reverse the hypoglycemia. The very young have an increased risk of permanently reduced cognitive function as a long-term sequela of severe hypoglycemia. For this reason, a more relaxed degree of glucose control is necessary until the child matures (see Table 589-9).

Hypoglycemia can occur at any time of day or night. Early symptoms and signs (mild hypoglycemia) may occur with a sudden decrease in blood glucose to levels that do not meet standard criteria for hypoglycemia in children without diabetes. The child may show pallor, sweating, apprehension or fussiness, hunger, tremor, and tachycardia, all as a result of the surge in catecholamines as the body attempts to counter the excessive insulin effect. Behavioral changes such as tearfulness, irritability, and aggression are more prevalent in children. As glucose levels decline further, cerebral glucopenia occurs with drowsiness, personality changes, mental confusion, and impaired judgment (moderate hypoglycemia), progressing to inability to seek help and seizures or coma (severe hypoglycemia). Prolonged severe hypoglycemia can result in a depressed sensorium or stroke-like focal motor deficits that persist after the hypoglycemia has resolved. Although permanent sequelae are rare, severe hypoglycemia is frightening for the child and family and can result in significant reluctance to attempt even moderate glycemic control afterward.

Important counterregulatory hormones in children include growth hormone, cortisol, epinephrine, and glucagon. The latter 2 seem more critical in the older child. Many older patients with long-standing T1DM lose their ability to secrete glucagon in response to hypoglycemia. In the young adult, epinephrine deficiency may also develop as part of a general autonomic neuropathy. This substantially increases the risk of hypoglycemia because the early warning signals of a declining glucose level are as a result of catecholamine release. Recurrent hypoglycemic episodes associated with tight metabolic control may aggravate partial counterregulatory deficiencies, producing a syndrome of hypoglycemia unawareness and reduced ability to restore euglycemia (hypoglycemia-associated autonomic failure). Avoidance of hypoglycemia allows some recovery from this unawareness syndrome.

The most important factors in the management of hypoglycemia are an understanding by the patient and family of the symptoms and signs of the reaction and an anticipation of known precipitating factors such as gym or sports activities. Tighter glucose control increases the risk. Families should be taught to look for typical hypoglycemic scenarios or patterns in the home glucose log, so that they may adjust the insulin dose and avert predictable episodes. A source of emergency glucose should be available at all times and places, including at school and during visits to friends. If possible, it is important to document the hypoglycemia before treating, because some symptoms may not always be from hypoglycemia. Any child suspected of having a moderate to severe hypoglycemic episode should be treated before testing. It is important not to give too much glucose; 5-10 g should be given as juice or a sugar-containing carbonated beverage or candy, and the blood glucose checked 15-20 min later. Patients, parents, and teachers should also be instructed in the administration of glucagon when the child cannot take glucose orally. An injection kit should be kept at home and school. The intramuscular dose is 0.5 mg if the child weighs less than 20 kg and 1.0 mg if more than 20 kg. This produces a brief release of glucose from the liver. Glucagon often causes emesis, which precludes giving oral supplementation if the blood glucose declines after the glucagon effects have waned. Caretakers must then be prepared to take the child to the hospital for IV glucose administration, if necessary. Minidose glucagon (10 μg/kg of age up to a maximum of 150 μg subcutaneously) is effective in treating hypoglycemia in children with blood glucose less than 60 mg/dL who fail to respond to oral glucose and remain symptomatic.

### Dawn Phenomenon and Somogyi Phenomenon

There are several reasons that blood glucose levels increase in the early morning hours before breakfast. The most common is a simple decline in insulin levels. This usually results in routinely elevated morning glucose. The **dawn phenomenon** is thought to be mainly caused by overnight growth hormone secretion and increased insulin clearance. It is a normal physiologic process seen in most adolescents without diabetes, who compensate with more insulin output. A child with T1DM cannot compensate. The dawn phenomenon is usually recurrent and modestly elevates most morning glucose levels.

Rarely, high morning glucose is caused by the **Somogyi phenomenon**, a theoretical rebound from late-night or early-morning hypoglycemia, thought to be from an exaggerated counterregulatory response. It is unlikely to be a common cause, in that most children remain hypoglycemic (do not rebound) once nighttime glucose levels decline. Continuous glucose monitoring systems may help clarify ambiguously elevated morning glucose levels.
Behavioral/Psychologic Aspects and Eating Disorders

Diabetes in a child affects the lifestyle and interpersonal relationships of the entire family. Feelings of anxiety and guilt are common in parents. Similar feelings, coupled with denial and rejection, are equally common in children, particularly during the rebellious teenage years. Family conflict has been associated with poor treatment adherence and poor metabolic control among youths with T1DM. On the other hand, it has been shown that shared responsibility is consistently associated with better psychologic health, good self-care behavior, and good metabolic control, whereas responsibility assumed by either the child or parent alone does not have outcomes that are equally successful. In some cases, links of shared responsibility to health outcomes were stronger among older adolescents. However, no specific personality disorder or psychopathology is characteristic of diabetes; similar feelings are observed in families with other chronic disorders.

COGNITIVE FUNCTION

There is increasing agreement that children with T1DM are at higher risk of developing small differences in cognitive abilities compared to healthy age-matched peers. Evidence suggests that early-onset diabetes (younger than 7 yr) is associated with cognitive difficulties compared to late-onset diabetes and healthy controls. The cognitive difficulties observed were primarily learning and memory skills (both verbal and visual) and attention/executive function skills. It is likely that the impact of diabetes on pediatric cognition appears shortly after diagnosis. Indeed, it has been observed that early-onset diabetes and longer duration of diabetes in children with diabetes adversely affect their school performance and educational achievements.

COPING STYLES

Children and adolescents with T1DM are faced with a complex set of developmental changes as well as shifting burdens of the disease. Adjustment problems might affect psychologic well-being and the course of the disease by impacting self-management and leading to poor metabolic control. Coping styles refer to typical habitual preferences for ways of approaching problems and might be regarded as strategies that people generally use to cope across a wide range of stressors. Problem-focused coping refers to efforts directed toward rational management of a problem, and it is aimed at changing the situation causing distress. On the other hand, emotion-focused coping implies efforts to reduce emotional distress caused by the stressful event and to manage or regulate emotions that might accompany or result from the stressor. In adolescents with diabetes, avoidance coping and venting emotions have been found to predict poor illness-specific self-care behavior and poor metabolic control. Patients who use more mature defenses and exhibit greater adaptive capacity are more likely to adhere to their regimen. Coping strategies seem to be age dependent, with adolescents using more avoidance coping than younger children with diabetes.

NONADHERENCE

Family conflict, denial, and feelings of anxiety or loss of control find expression in nonadherence to instructions regarding nutritional and insulin therapy and in noncompliance with self-monitoring. When adolescents perceive their parents' involvement as criticism, or when they externalize behavior problems, such behaviors interfere with adherence and may result in deterioration of glycemic control. Such behaviors are very common, whereas episodes of deliberate overdosage with insulin resulting in hypoglycemia, or omission of insulin resulting in ketoacidosis, are far less prevalent. They may, however, be pleas for psychologic help or be manipulative attempts to escape an environment perceived as undesirable or intolerable; occasionally, they may be manifestations of suicidal intent. Frequent admissions to the hospital for ketoacidosis or hypoglycemia should arouse suspicion of an underlying emotional conflict. Overprotection on the part of parents is common and often is not in the best interest of the adolescent patient. Feelings of being different or of being alone, or both, are common and must be acknowledged, but may be addressed by tailoring the insulin administration and timing of meals and blood sugar testings in order to allow for a more individualized lifestyle. Families and patients worry about the risk of complications from diabetes, aggregating what they know about type I and type II diabetes, and worry about the decreased life span. Unfortunately, misinformation abounds about the risks of the development of diabetes in siblings or offspring and of pregnancy in young diabetic women. Even appropriate information may cause further anxiety.

All of these issues must be spoken about at the outset, and many of these problems can be averted through continued empathic counseling based on correct information, focusing on normality and on planning to be a productive member of society. Recognizing the potential impact of these problems, peer discussion groups have been organized in many locales; feelings of isolation and frustration tend to be lessened by the sharing of common problems. Summer camps for diabetic children afford an excellent opportunity for learning and sharing under expert supervision. Education about the pathophysiology of diabetes, insulin dose, techniques of administration, nutrition, exercise, and hypoglycemic reactions can be reinforced by medical and paramedical personnel. The presence of numerous peers with similar problems offers new insights to the diabetic child. Residential treatment for children and adolescents with difficult to manage T1DM is an option available only in some centers.

ANXIETY AND DEPRESSION

It has been shown that there are significant correlations between poor metabolic control and depressive symptoms, a high level of anxiety, or a previous psychiatric diagnosis. In a similar way, poor metabolic control is related to higher levels of personal, social, school maladjustment, or family environment dissatisfaction. It is estimated that 20-26% of adolescent patients may develop major depressive disorder. The prevalence of depression is 2-fold greater than controls in children with diabetes and 3-fold greater in adolescents. The course characteristics of depression in young diabetic subjects and psychiatric control subjects appear to be similar; however, eventual propensity of diabetic youths for more protracted depressions is greater and there is a higher risk of recurrence among young diabetic females. On balance, anxiety and depression play an important and complex role in T1DM; their relationship to metabolic control does not yet appear clear. Therefore, the health care providers managing a child or adolescent with diabetes should be aware of their pivotal role as counselor and advisor and should closely monitor the mental health of patients with diabetes.

FEAR OF SELF-INJECTING AND SELF-TESTING

Extreme fear of self-injecting insulin (injection phobia) is likely to compromise glycemic control as well as emotional well-being. Likewise, fear of finger-pricks can be a source of distress and may seriously hamper self-management. Children and adolescents may either omit insulin dosing or refuse to rotate their injection sites because repeated injection in the same site is associated with less pain sensation. Failure to rotate injection sites results in subcutaneous scar formation (lipohypertrophy). Insulin injection into the lipohypertrophic skin is usually associated with poor insulin absorption and/or insulin leakage with resultant suboptimal glycemic control. Children and adolescents with injection phobia and fear of self-testing can be counseled by a trained behavioral therapist and benefit from such techniques as desensitization and biofeedback to attenuate pain sensation and psychologic distress associated with these procedures. Another possibility is to consider using an indwelling subcutaneous soft cannula to minimize the discomfort of repeated injections.

EATING DISORDERS

Treatment of T1DM involves constant monitoring of food intake. In addition, improved glycemic control is sometimes associated with increased weight gain. In adolescent females, these 2 factors, along with individual, familial, and socioeconomic factors, can lead to an increased incidence of both nonspecific and specific eating disorders, which can disrupt glycemic control and increase the risk of long-term complications. Eating disorders and subthreshold eating disorders are almost
twice as common in adolescent females with T1DM as in their non-diabetic peers. The reports of the frequencies of specific (anorexia or bulimia nervosa) eating disorders vary from 1.0-6.9% among female patients with T1DM. The prevalence of nonspecific and subthreshold eating disorders is 9% and 14%, respectively. Approximately 11% of T1DM adolescent females take less insulin than prescribed in order to lose weight. Among adolescent females with an eating disorder, approximately 42% of patients misuse insulin, whereas the estimates of insulin misuse prevalence in subthreshold and nondiordered eating groups are 18% and 6%, respectively. Although there is little information regarding the prevalence of eating disorders among male adolescents with T1DM, available data suggest normal eating attitudes in most. Among healthy adolescent males who participate in wrestling, however, the drive to lose weight has led to the seasonal, transient development of abnormal eating attitudes and behaviors, which may lead to insulin dose omission in order to lose weight.

When behavioral/psychologic problems and/or eating disorders are assumed to be responsible for poor adherence with the medical regimen, referral for psychologic evaluation and management is indicated. Behavioral therapists and psychologists usually form part of the pediatric diabetes team in most centers and can help assess and manage emotional and behavioral disorders in diabetic children. Evaluation of nurse-delivered motivational enhancement with and without cognitive behavior therapy in adults revealed the combined therapy resulted in modest improvement in glycemic control. However, motivational enhancement therapy alone did not improve glycemic control. While in some studies the effect of therapist-delivered motivational enhancement therapy on glycemic control in adolescents with T1DM lasted as long as intensive individualized counseling continued, in other studies, motivational interviewing was shown to be an effective method of facilitating changes in a teenager’s behavior with T1DM with corresponding improvement in glycemic control.

**Management During Infections**

Although infections are no more common in diabetic children than in nondiabetic ones, they can often disrupt glucose control and may precipitate DKA. In addition, the diabetic child is at increased risk of dehydration if hyperglycemia causes an osmotic diuresis or if ketosis causes emesis. Counterregulatory hormones associated with stress blunt insulin action and elevate glucose levels. If anorexia occurs from causes emesis. Counterregulatory hormones associated with stress dehydration if hyperglycemia causes an osmotic diuresis or if ketosis precipitate DKA. In addition, the diabetic child is at increased risk of nondiabetic ones, they can often disrupt glucose control and may exacerbate fluid losses, and may initiate DKA. On the other hand, caloric intake is usually restricted, which decreases glucose levels. The net effect is as difficult to predict as during an infection. Vigilant monitoring and frequent insulin adjustments are required to maintain euglycemia and avoid ketosis.

Maintaining glucose control and avoiding DKA are best accomplished with IV insulin and fluids. A simple insulin adjustment scale based on the patient’s weight and blood glucose level can be used in most situations (Table 589-11). The IV insulin is continued after surgery as the child begins to take oral fluids; the IV fluids can be steadily decreased as oral intake increases. When full oral intake is achieved, the IV may be capped and subcutaneous insulin begun. When surgery is elective, it is best performed early in the day, allowing the patient maximal recovery time to restart oral intake and subcutaneous insulin therapy. When elective surgery is brief (less than 1 hr) and full oral intake is expected shortly afterward, one may simply monitor the blood glucose hourly and give a dose of insulin analog according to the child’s home glucose correction scale. If glargine or detemir is used as the basal insulin, a full dose is given the evening before planned surgery. If NPH or Lente is used, one half of the morning dose is given before surgery. The child should not be discharged until blood glucose levels are stable and oral intake is tolerated.

**Management During Surgery**

Surgery can disrupt glucose control in the same way as can intercurrent infections. Stress hormones associated with the underlying condition as well as with surgery itself cause insulin resistance. This increases glucose levels, exacerbates fluid losses, and may initiate DKA. On the other hand, caloric intake is usually restricted, which decreases glucose levels. The net effect is as difficult to predict as during an infection. Vigilant monitoring and frequent insulin adjustments are required to maintain euglycemia and avoid ketosis.

Maintaining glucose control and avoiding DKA are best accomplished with IV insulin and fluids. A simple insulin adjustment scale based on the patient’s weight and blood glucose level can be used in most situations (Table 589-11). The IV insulin is continued after surgery as the child begins to take oral fluids; the IV fluids can be steadily decreased as oral intake increases. When full oral intake is achieved, the IV may be capped and subcutaneous insulin begun. When surgery is elective, it is best performed early in the day, allowing the patient maximal recovery time to restart oral intake and subcutaneous insulin therapy. When elective surgery is brief (less than 1 hr) and full oral intake is expected shortly afterward, one may simply monitor the blood glucose hourly and give a dose of insulin analog according to the child’s home glucose correction scale. If glargine or detemir is used as the basal insulin, a full dose is given the evening before planned surgery. If NPH or Lente is used, one half of the morning dose is given before surgery. The child should not be discharged until blood glucose levels are stable and oral intake is tolerated.

Basal insulin: glargine or detemir basal insulin should be given at the usual dose and time. NPH and Lente should be reduced by half if blood glucose <150 mg/dL and the oral intake is limited.

Oral fluids: sugar-free if blood glucose >250 mg/dL (14 mmol/L); sugar-containing if blood glucose <250 mg/dL.

Call physician or nurse if blood glucose remains elevated after 3 extra doses, if blood glucose remains less than 70 mg/dL and child cannot take oral supplement; if dehydration occurs.

*Give insulin based on individualized dosing schedule. Also give usual dose for carbohydrate intake if glucose >150 mg/dL.

1 For home serum ketones <1.5 mmol/L per commercial kit.

2 For home serum ketones >1.5 mmol/L.
LONG-TERM COMPLICATIONS: RELATION TO GLYCEMIC CONTROL

Complications of DM can be divided into 3 major categories: (1) microvascular complications, specifically, retinopathy and nephropathy; (2) macrovascular complications, particularly accelerated coronary artery disease, cerebrovascular disease, and peripheral vascular disease; and (3) neuropathies, both peripheral and autonomic, affecting a variety of organs and systems (Table 589-12). In addition, cataracts may occur more frequently.

Diabetic retinopathy is the leading cause of blindness in the United States in adults age 20-65 yr. The risk of diabetic retinopathy after 15 yr duration of diabetes is 98% for individuals with T1DM and 78% for those with T2DM. Rates for diabetic retinopathy range from close to 15% to up to 30%. Lens opacities (caused by glycation of tissue proteins and activation of the polyl pathway) are present in at least 5% of those younger than age 19 yr. The metabolic control has an impact on the development of this complication, as prevalence rates are substantially higher with increased duration of diabetes, and higher HbA1c, blood pressure, and cholesterol. Independent of duration, the prevalence of diabetic retinopathy is higher in T1DM. However, genetic factors also have a role, because only 50% of patients develop proliferative retinopathy. The earliest clinically apparent manifestations of diabetic retinopathy are classified as nonproliferative or background diabetic retinopathy—microaneurysms, dot and blot hemorrhages, hard and soft exudates, venous dilation and beading, and intraretinal microvascular abnormalities. These changes do not impair vision. The more severe form is proliferative diabetic retinopathy, which manifests by neovascularization, fibrous proliferation, and preretinal and vitreous hemorrhages. Proliferative retinopathy, if not treated, is relentlessly progressive and impairs vision, leading to blindness. The mainstay of treatment is panretinal laser photocoagulation. In advanced diabetic eye disease—manifested by severe vitreous hemorrhage or fibrosis, often with retinal detachment—vitrectomy is an important therapeutic modality. Eventually, the eye disease becomes quiescent, a stage termed involutional retinopathy. A separate subtype of retinopathy is diabetic maculopathy, which is manifested by severe macular edema impairing central vision, for which focal laser photocoagulation may be effective.

Guidelines suggest that diabetic patients have an initial dilated and comprehensive examination by an ophthalmologist shortly after the diagnosis of diabetes is made in patients with T2DM, and within 3-5 yr after the onset of T1DM (but not before age 10 yr). Any patients with visual symptoms or abnormalities should be referred for ophthalmologic evaluation. Subsequent evaluations for both T1DM and T2DM patients should be repeated annually by an ophthalmologist who is experienced in diagnosing the presence of diabetic retinopathy and is knowledgeable about its management (see Table 589-12).

Diabetic nephropathy is the leading known cause of end-stage renal disease (ESRD) in the United States. Most ESRD from diabetic nephropathy is preventable. Diabetic nephropathy affects 20-30% of patients with T1DM and 15-20% of T2DM patients 20 yr after onset. The mean 5 yr life expectancy for patients with diabetes-related ESRD is less than 20%. The increased mortality risk in long-term T1DM may be due to nephropathy, which may account for approximately 50% of deaths. The risk of nephropathy increases with duration of diabetes (up until 25-30 yr duration, after which this complication rarely begins), degree of metabolic control, and genetic predisposition to essential hypertension. Only 30-40% of patients affected by T1DM eventually experience ESRD. The glycation of tissue proteins results in glomerular basement membrane thickening. The course of diabetic nephropathy is slow. An increased urinary albumin excretion rate of 30-300 mg/24 hr (20-200 µg/min)—microalbuminuria—can be detected and constitutes an early stage of nephropathy from intermittent to persistent (incipient), which is commonly associated with glomerular hyperfiltration and blood pressure elevation. As nephropathy evolves to early overt stage with proteinuria (albumin excretion rate >300 mg/24 hr, or >200 µg/min), it is accompanied by hypertension. Advanced-stage nephropathy is defined by a progressive decline in renal function (declining glomerular filtration rate and elevation of serum blood urea and creatinine), progressive proteinuria, and

ACE, angiotensin-converting enzyme; T1DM, type 1 diabetes mellitus; T2DM, type 2 diabetes mellitus; TSH, thyroid-stimulating hormone

hypertension. Progression to ESRD is recognized by the appearance of uremia, the nephritic syndrome, and the need for renal replacement (transplantation or dialysis).

Screening for diabetic nephropathy is a routine aspect of diabetes care (see Table 389-12). The American Diabetes Association recommends yearly screening for individuals with T2DM and yearly screening for those with T1DM after 5 yr duration of disease (but not before puberty). A random spot urine sample for albumin to creatinine ratio is obtained. Abnormal results should be confirmed by 2 additional specimens on separate days because of the high variability of albumin excretion in patients with diabetes. Short-term hyperglycemia, strenuous exercise, urinary tract infections, marked hypertension, heart failure, and acute febrile illness can cause transient elevation urinary albumin excretion. There is marked day-to-day variability in albumin excretion, so at least 2 of 3 collections done in a 3-6 mo period should show elevated levels before microalbuminuria is diagnosed and treatment is started. Once albuminuria is diagnosed, a number of factors attenuate the effect of hyperfiltration on kidneys: (1) meticulous control of hyperglycemia, (2) aggressive control of systemic blood pressure, (3) selective control of arteriolar dilation by use of angiotensin-converting enzyme inhibitors (thus decreasing transglomerular capillary pressure), and (4) dietary protein restriction (because high protein intake increases the renal perfusion rate). Tight glycemic control will delay the progression of microalbuminuria and slow the progression of diabetic nephropathy. Previous extensive therapy of diabetes has a persistent benefit for 7-8 yr and may delay or prevent the development of diabetic nephropathy.

DIABETIC NEUROPATHY

Both the peripheral and autonomic nervous systems can be involved, and adolescents with diabetes can show early evidence of neuropathy. This complication can be traced to the metabolic effects of hyperglycemia and/or other effects of insulin deficiency on the various constituents of the peripheral nerve. The polyol pathway, nonenzymatic glycation, and/or disturbances of myoinositol metabolism affecting 1 or more cell types in the multicellular constituents of the peripheral nerve appear likely to have an inciting role. The role of other factors, such as possible direct neurotoxic effects of insulin, insulin-related growth factors, nitric oxide, and stress proteins, seems to be relevant. Peripheral neuropathy may first present in some adolescents with a long-standing history of diabetes. Using quantitative sensory testing, abnormal cutaneous thermal perception is a common finding in both upper and lower limbs in neurologically asymptomatic young diabetic patients. Heat-induced pain threshold in the hand is correlated with the duration of the diabetes. There is no correlation between quantitative sensory testing scores and metabolic control. Subclinical motor nerve impairment as manifested by reduced sensory nerve conduction velocity and sensory nerve action potential amplitude can be detected during late puberty and after puberty in approximately 10% of adolescents. Poor metabolic control during puberty appears to induce deteriorating peripheral neural function in young patients. An early sign of autonomic neuropathy such as decreased heart rate variability may present in adolescents with a history of long-standing disease and poor metabolic control. A number of therapeutic strategies have been attempted with variable results. These treatment modalities include (1) improvement in metabolic control, (2) use of aldose reductase inhibitors to reduce by-products of the polyol pathway, (3) use of α-lipoic acid (an antioxidant) that enhances tissue nitric oxide and its metabolites, (4) use of anticonvulsants (e.g., lorazepam, valproate, gabapentin, carbamazepine, pregabalin, phenytoin, tiagabine, and topiramate) for treatment of neuropathic pain, and (5) antidepressants (amitriptyline, imipramine, and selective serotonin reuptake inhibitors). Additional medications include antiarrhythmics such as lidocaine, topical analgesics, and nonsteroidal antiinflammatory drugs.

Other quite rarely noted complications in diabetic children include dwarfism associated with a glycogen-laden enlarged liver (Mauriac syndrome), osteopenia, and a syndrome of limited joint mobility associated with tight, waxy skin; growth impairment; and maturational delay. The Mauriac syndrome is related to chronic underinsulization; it is much less common since longer-acting insulins have become available. Clinical features of Mauriac syndrome include moon face, protuberant abdomen, proximal muscle wasting, and enlarged liver from fat and glycogen infiltration. The syndrome of limited joint mobility is frequently associated with the early development of diabetic microvascular complications, such as retinopathy and nephropathy, which may appear before 18 yr of age. In the past decade or two, the prevalence of limited joint mobility has significantly decreased, which is attributed to the improved overall metabolic control of children and adolescents with T1DM.

PROGNOSIS

T1DM is a serious, chronic disease. It has been estimated that the average life span of individuals with diabetes is approximately 10 yr shorter than that of the nondiabetic population. Although diabetic children eventually attain a height within the normal adult range, puberty may be delayed, and the final height may be less than the genetic potential. From studies in identical twins, it is apparent that despite seemingly satisfactory control, the diabetic twin manifests delayed puberty and a substantial reduction in height when onset of disease occurs before puberty. These observations indicate that, in the past, conventional criteria for judging control were inadequate and that adequate control of T1DM was almost never achieved by routine means.

The introduction of portable devices (insulin pumps) that can be programmed to provide CSII with meal-related boluses is 1 approach to the resolution of these long-term problems. In selected individuals, nearly normal patterns of blood glucose and other indices of metabolic control, including HbA1c, have been maintained for several years. This approach, however, should be reserved for highly motivated persons committed to rigorous self-monitoring of blood glucose who are alert to the potential complications, such as mechanical failure of the infusion device causing hyperglycemia or hypoglycemia and to infection at the site of catheter insertion.

The changing pattern of metabolic control is having a profound influence on reducing the incidence and the severity of certain complications. For example, after 20 yr of diabetes, there is a decline in the incidence of nephropathy in T1DM in Sweden among children whose disease was diagnosed in 1971-1975 compared with in the preceding decade. In addition, in most patients with microalbuminuria in whom it was possible to obtain good glycemic control, microalbuminuria disappeared. This improved prognosis is directly related to metabolic control.

PANCREAS AND ISLET TRANSPLANTATION AND REGENERATION

In an attempt to cure T1DM, transplantation of a segment of the pancreas or of isolated islets has been performed in adults. These procedures are both technically demanding and associated with the risks of disease recurrence and complications of rejection or its treatment by immunosuppression. Long-term complications of immunosuppression include the development of malignancy. Some antirejection drugs, notably cyclosporine and tacrolimus, are toxic to the islets of Langerhans, impairing insulin secretion and even causing diabetes. Hence, segmental pancreas transplantation is generally only performed in association with transplantation of a kidney for a patient with ESRD due to diabetic nephropathy in which the immunosuppressive regimen is indicated for the renal transplantation. Several thousand such transplants have been performed in adults. With experience and newer immunosuppressive agents, functional survival of the pancreatic graft may be achieved for up to several years, during which time patients may be in metabolic control with no or minimal exogenous insulin and reversal of some of the microvascular complications. However, because children and adolescents with DM are not likely to have ESRD from their diabetes, pancreas transplantation as a primary treatment in children cannot be recommended.

Islet cell transplantation is challenging because of limited survival of the transplanted cells and because of rejection. Research continues to improve techniques for the yield, viability, and reduction of
immunogenicity of the islets of Langerhans for transplantation. An islet transplantation strategy (Edmonton protocol) infused isolated pancreatic islets into the portal vein of a group of adults with T1DM, along with immunosuppressive medications that had lower side-effect profiles than other drugs. While lasting insulin independence was initially low, engraftment and insulin independence have improved over the last decade, and over a thousand patients having undergone the procedure. There has been improved islet engraftment by the use of improved induction and maintenance immunosuppression. Still, in 5-y follow-up studies, only 1 in 4 maintained insulin independence, with an average duration of insulin independence in all of only about 15 mo. Long-term challenges remain the toxicity of immunosuppression, the limited procurement of viable tissue, and funding and limitations of engraftment itself.

Alternative means of generating β cells are being sought from islet expansion, encapsulated islet xenografts, human islet cell-lines, and stem cells. Regeneration of islets is an approach that could potentially cure T1DM because β-cell mass is actually dynamically regulated.

589.3 Type 2 Diabetes Mellitus
Britta M. Svoeren and Nicholas Jospe

Formerly known as non–insulin dependent diabetes or adult-onset diabetes, T2DM is a heterogeneous disorder, characterized by peripheral insulin resistance and failure of the β cell to keep up with increasing insulin demand. Patients with T2DM have relative rather than absolute insulin deficiency. Generally, they are not ketosis prone, but ketoacidosis may develop in some circumstances. The specific etiology is not known, but these patients do not have autoimmune destruction of β cells, nor do they have any of the known causes of secondary diabetes.

NATURAL HISTORY
T2DM is considered a polygenic disease aggravated by environmental factors, such as low physical activity and excessive caloric intake. Most patients are obese, although the disease can occasionally be seen in normal weight individuals. Asians in particular appear to be at risk for T2DM at lower degrees of total adiposity. Some patients may not necessarily meet overweight or obese criteria for age and gender despite abnormally high percentage of body fat in the abdominal region. Obesity, in particular, central obesity, is associated with the development of insulin resistance. In addition, patients who are at risk for developing T2DM exhibit decreased glucose-induced insulin secretion. Obesity does not lead to the same degree of insulin resistance in all individuals and even those who develop insulin resistance do not necessarily exhibit impaired β-cell function. Thus, many obese individuals have some degree of insulin resistance but compensate for it by increasing insulin secretion. Those individuals who are unable to adequately compensate for insulin resistance by increasing insulin secretion, develop IGT and impaired fasting glucose (usually, although not always, in that order). Hepatic insulin resistance leads to excessive hepatic glucose output (failure of insulin to suppress hepatic glucose output), while skeletal muscle insulin resistance leads to decreased glucose uptake in a major site of glucose disposal. Over time hyperglycemia worsens, a phenomenon that has been attributed to the deleterious effect of chronic hyperglycemia (glucotoxicity) or chronic hyperlipidemia (lipotoxicity) on β-cell function and is often accompanied by increased triglyceride content and decreased insulin gene expression. At some point, blood glucose elevation meets the criteria for diagnosis of T2DM (see Table 589-2), but most patients with T2DM remain asymptomatic for months to years after this point because hyperglycemia is moderate and symptoms are not as dramatic as the polyuria and weight loss accompanying T1DM. Weight gain may even continue. The prolonged hyperglycemia may be accompanied by the development of microvascular and macrovascular complications. In time, β-cell function can decrease to the point that the patient has absolute insulin deficiency and becomes dependent on exogenous insulin. In T2DM, insulin deficiency is rarely absolute, so patients usually do not need insulin to survive. Nevertheless, glycemic control can be improved by exogenous insulin. Although DKA is uncommon in patients with T2DM, it can occur and is usually associated with the stress of another illness such as severe infection. DKA tends to be more common in African-American patients than in other ethnic groups. Although it is generally believed that autoimmune destruction of pancreatic β cells does not occur in T2DM, autoimmune markers of T1DM—namely, glutamic acid decarboxylase antibody, ICA512, and insulin-associated autoantibody—may be positive in up to one third of the cases of adult onset T2DM. The presence of these autoimmune markers does not rule out T2DM in children and adolescents. At the same time, because of the general increase in obesity, the presence of obesity does not preclude the diagnosis of T1DM. Although the majority of newly diagnosed children and adolescents can be confidently assigned a diagnosis of T1DM or T2DM, a few exhibit features of both types and are difficult to classify.

EPIDEMIOLOGY
National Health and Nutritional Examination Surveys data (from 1999-2002) show that the prevalence of T2DM in 12-19 yr olds in the United States is 1.46 in 1,000. The Southeastern Aerosol Research and Characterization (SEARCH) study found that the prevalence of type 2 diabetes in the 10-19 yr old age group in the United States was 15% in 2001 and it is likely that this proportion has increased over time. Certain ethnic groups appear to be at higher risk; for example, Native Americans, Hispanic Americans, and African-Americans (in that order) have higher incidence rates than white Americans. Although a majority of children presenting with diabetes still have T1DM, the percentage of children presenting with T2DM is increasing and represents up to 50% of the newly diagnosed children in some centers.

Prevalence in the rest of the world varies widely and accurate data are not available for many countries, but it is clear that the prevalence is increasing in every part of the world. Asians in general seem to develop T2DM at lower body mass index levels than Europeans. In conjunction with their low incidence of type 1 diabetes, this means that T2DM accounts for a higher proportion of childhood diabetes in many Asian countries.

The epidemic of T2DM in children and adolescents parallels the emergence of the obesity epidemic. Although obesity itself is associated with insulin resistance, diabetes does not develop until there is some degree of failure of insulin secretion. Thus, when measured, insulin secretion in response to glucose or other stimuli is always lower in persons with T2DM than in control subjects matched for age, sex, weight, and equivalent glucose concentration.

GENETICS
T2DM has a strong genetic component; concordance rates among identical twins are in the 60-90% range. It should be kept in mind, however, that twinning itself increases the risk of T2DM (because of intrauterine growth restriction) and this may distort estimates of genetic risk. In at least 1 study from Denmark, both monozygotic and dizygotic twins have a lifetime concordance of T2DM of around 70%, indicating that shared environmental factors (including the prenatal environment) may play a large role in the development of T2DM. The genetic basis for T2DM is complex and incompletely defined; no single identified defect predominates as does the HLA association with T1DM. Genomewide association studies have now identified certain genetic polymorphisms that are associated with increased T2DM risk in most populations studied; the most consistently identified are variants of the TCF7L2 (transcription factor 7–like 2) gene, which may have a role in β-cell function. Other identified risk alleles include variants in PPARG and KCNJ11 as well as many others. But to date, all these identified variants explain only a small portion (probably less than 20%) of the population risk of diabetes and in many cases the mechanism by which these polymorphisms confer risk of T2DM is not clear.

EPIGENETICS AND FETAL PROGRAMMING
Low birthweight and intrauterine growth restriction are associated with increased risk of T2DM. This risk appears to be higher in
low-birthweight infants who gain weight more rapidly in the 1st few years of life. These findings have led to the formulation of the “thrift phenotype” hypothesis, which postulates that poor fetal nutrition somehow programs these children to maximize storage of nutrients and makes them more prone to future weight gain and development of diabetes. Epigenetic modifications may play a role in this phenomenon, but the detailed molecular mechanisms involved have yet to be determined. Whatever the exact mechanism, prenatal and early childhood environments play an important role in the pathogenesis of T2DM and may do so by epigenetic modification of the DNA (in addition to other factors).

ENVIRONMENTAL AND LIFESTYLE-RELATED RISK FACTORS

Obesity is the most important lifestyle factor associated with development of T2DM. This, in turn, is associated with the intake of high-energy foods, physical inactivity, TV viewing (“screen time”), and low socioeconomic status (in developed countries). Maternal smoking also increases the risk of diabetes and obesity in the offspring. Interestingly, smoking by young adults also increases their own risk of diabetes by as yet unknown mechanisms. In addition, sleep deprivation and psychosocial stress are associated with increased risk of obesity in childhood and with IGT in adults, possibly via overactivation of the hypothalamic-pituitary-adrenal axis. Many antipsychotics (especially the atypical antipsychotics like olanzapine and quetiapine) and antidepressants (both tricyclic antidepressants and newer antidepressants like fluoxetine and paroxetine) induce weight gain. In addition to the risk conferred by increased obesity, some of these medications may also have a direct role in causing insulin resistance, β-cell dysfunction, leptin resistance, and activation of inflammatory pathways. To complicate matters further, there is evidence that schizophrenia and depression themselves increase the risk of T2DM and the metabolic syndrome, independent of the risk conferred by drug treatment. As a result, both obesity and T2DM are more prevalent in this population, and with increasing use of antipsychotics and antidepressants in the pediatric population, this association is likely to become stronger.

CLINICAL FEATURES

In the United States, T2DM in children is more likely to be diagnosed in Native American, Hispanic American, and African-American youth, with the highest incidence being reported in Pima Indian youth. While cases may be seen as young as 6 yr of age, most are diagnosed in adolescence and incidence increases with increasing age. Family history of T2DM is present in practically all cases. Typically, patients are obese and present with mild symptoms of polyuria and polydipsia, or asymptomatic and detected on screening tests. Presentation with DKA occurs in up to 10% of cases. Physical examination frequently reveals the presence of acanthosis nigricans, most commonly on the neck and in other flexural areas. Other findings may include striae and an increased waist:hip ratio. Laboratory testing reveals elevated HbA1c levels. Hyperlipidemia characterized by elevated triglycerides and low-density lipoprotein cholesterol levels is commonly seen in patients with T2DM at diagnosis. Consequently, lipid screening is indicated in all new cases of T2DM. Because hyperglycemia develops slowly and patients may be asymptomatic for months or years after they develop T2DM, screening for T2DM is recommended in high-risk children (Table 589-13). The American Diabetes Association recommends that all youth who are overweight and have at least 2 other risk factors be tested for T2DM beginning at age 10 yr or at the onset of puberty and every 2 yr after that. Risk factors include family history of T2DM in 1st- or 2nd-degree relatives, history of gestational diabetes in the mother, belonging to certain ethnic groups (i.e., Native American, African-American, Hispanic, or Asian/Pacific Islander groups) and having signs of insulin resistance (e.g., acanthosis nigricans, hypertension, dyslipidemia, or polycystic ovary syndrome). The current recommendation is to use fasting blood glucose as a screening test, but some authorities now recommend that HbA1c be used as a screening tool. In borderline or asymptomatic cases, the diagnosis may be confirmed using a standard oral glucose tolerance test, but this test is not required if typical symptoms are present or fasting plasma glucose or HbA1c is clearly elevated on 2 separate occasions.

TREATMENT

Type 2 diabetes is a progressive syndrome that gradually leads to complete insulin deficiency during the patient’s life. A systematic approach for treatment of T2DM should be implemented according to the natural course of the disease, including adding insulin when hypoglycemic oral agent failure occurs. Nevertheless, lifestyle modification (diet and exercise) is an essential part of the treatment regimen, and consultation with a dietitian is usually necessary. There is no particular dietary or exercise regimen that has been conclusively shown to be superior but most centers recommend a low-calorie, low-fat diet and 30-60 min of physical activity at least 5 times/wk. Screen time should be limited to 1-2 hr/day. Children with T2DM often come from household environments with a poor understanding of healthy eating habits. Commonly observed behaviors include skipping meals, heavy snacking, and excessive daily television viewing, video game playing, and computer use. Adolescents engage in non-appetite-based eating (i.e., emotional eating, television-cued eating, boredom) and cyclic dieting (“yo-yo” dieting). Treatment in these cases is frequently challenging and may not be successful unless the entire family buys into the need to change their unhealthy lifestyle.

It is recommended that oral hypoglycemic agents be introduced at the time of diagnosis (Table 589-14). Patients who present with DKA or with markedly elevated HbA1c (>9.0%) will require treatment with insulin using protocols similar to those used for treating T1DM. Once blood glucose levels are under control, most cases can be managed with oral hypoglycemic agents and lifestyle interventions, but some patients will continue to require insulin therapy.

The most commonly used and the only FDA-approved oral agent for the treatment of T2DM in children and adolescents is metformin. Renal function must be assessed before starting metformin as impaired renal function has been associated with potentially fatal lactic acidosis. Significant hepatic dysfunction is also a contraindication to metformin use, although mild elevations in liver enzymes may not be an absolute contraindication. The usual starting dose is 500 mg once daily. This may be increased to a maximum dose of 2,000 mg/day. Abdominal symptoms are common early in the course of treatment, but in most cases they will resolve with time.

Other agents such as thiazolidinediones, sulfonylureas, acarbose, pramlintide, and incretin mimetics are being used routinely in adults but are not used as commonly in pediatrics. Sulfonylureas are widely used in adults, but experience in pediatrics is limited. Sulfonylureas cause insulin release by closing the potassium channel (KATP) on β
cells. They are occasionally used when metformin monotherapy is unsuccessful or contraindicated for some reason (use in certain forms of neonatal diabetes is discussed in the section on neonatal diabetes). Thiazolidinediones are not approved for use in pediatrics. Pramlintide (Symlin) is an analog of IAPP (islet amyloid polypeptide), which is a peptide that is cosecreted with insulin by the β cells and acts to delay gastric emptying, suppress glucagon, and possibly suppress food intake. It is not yet approved for pediatric use. Incretins are gut-derived peptides like GLP-1, GLP-2, and GIP (glucose-dependent insulinotropic peptide, previously known as gastric inhibitory protein) that are secreted in response to meals and act to enhance insulin secretion and action, suppress glucagon production, and delay gastric emptying (among other actions). GLP-1 analogs (e.g., exenatide) and agents that prolong endogenous GLP-1 action (e.g., sitagliptin) are now available for use in adults but are not yet approved for use in children; they may be associated with side effects such as hepatic injury and pancreatitis.

COMPLICATIONS
In the SEARCH study of diabetes in youth, 92% of the patients with T2DM had 2 or more elements of the metabolic syndrome (hypertension, hypertriglyceridemia, decreased high-density lipoprotein, increased waist circumference), including 70% with hypertension. In addition, the incidence of microalbuminuria and diabetic retinopathy appears to be higher in T2DM than it is in T1DM. In the SEARCH study, the incidence of microalbuminuria among patients who had T2DM of less than 5 yr duration was 7-22%, while retinopathy was present in 18.3%. Thus, all adolescents with T2DM should be screened for hypertension and lipid abnormalities and screening for microalbuminuria and retinopathy may be indicated even earlier than it is in T1DM. Sleep apnea and fatty liver disease are being diagnosed with increasing frequency and may necessitate referral to the appropriate specialists. Complications associated with all forms of diabetes and recommendations for screening are noted in Table 589-12; Table 589-15 lists additional conditions particularly associated with T2DM.

PREVENTION
The difficulties in achieving good glucose control and preventing diabetes complications make prevention a compelling strategy. This is particularly true for T2DM, which is clearly linked to modifiable risk factors (obesity, a sedentary lifestyle). The Diabetes Prevention Program was designed to prevent or delay the development of T2DM in adult individuals at high risk by virtue of IGT. The Diabetes Prevention Program results demonstrated that intensified lifestyle or drug intervention in individuals with IGT prevented or delayed the onset of T2DM. The results were striking. Lifestyle intervention reduced the diabetes incidence by 58%; metformin reduced the incidence by 31% compared with placebo. The effects were similar for men and women and for all racial and ethnic groups. Lifestyle interventions are believed to have similar beneficial effects in obese adolescents with IGT. Screening is indicated for at-risk patients (see Table 589-13).

589.4 Other Specific Types of Diabetes

Britta M. Svoren and Nicholas Jospe

Most cases of diabetes in children as well as adults fall into the 2 broad categories of type 1 and type 2 diabetes, but up to 4% of cases are caused by single-gene disorders. These disorders include hereditary defects of β-cell function and insulin action, as well as rare forms of mitochondrial diabetes.

**GENETIC DEFECTS OF β-CELL FUNCTION**

**Maturity-Onset Diabetes of Youth**

Several forms of diabetes are associated with monogenic defects in β-cell function. Before these genetic defects were identified, this subset of diabetics was diagnosed on clinical grounds and described by the term MODY. This subtype of DM consists of a group of heterogeneous clinical entities that are characterized by onset before 25 yr, autosomal dominant inheritance, and a primary defect in insulin secretion. Strict criteria for the diagnosis of MODY include diabetes in at least 3 generations with autosomal dominant transmission and diagnosis before age 25 yr in at least 1 affected subject. Mutations have been found in at least 10 different genes, accounting for the dominantly inherited monogenic defects of insulin secretion, for which the term MODY is used. The American Diabetes Association groups these disorders together under the broader category of “genetic defects of β-cell function.” Eleven of these defects typically meet the clinical criteria for the diagnosis of MODY and are listed in Table 589-16. Just 3 of them (MODY2 and MODY3 and MODY5) account for 90% of the cases in this category in European populations, but the distribution may be different in other ethnic groups. Except for MODY2 (which is caused by mutations in the enzyme glucokinase), all other forms are caused by genetic defects in various transcription factors (Table 589-16).

**MODY2**

This is the second most common form of MODY and accounts for approximately 15-30% of all patients diagnosed with MODY. Glucokinase plays an essential role in β-cell glucose sensing and heterozygous mutations in this gene lead to mild reductions in pancreatic β-cell response to glucose. Homozygotes with the same mutations are completely unable to secrete insulin in response to glucose and develop a form of permanent neonatal diabetes. Patients with heterozygous mutations have a higher threshold for insulin release but are able to secrete insulin adequately once blood glucose rises above 7 mmol/L. This results in a relatively mild form of diabetes (HbA1c is usually less than 7%), with mild fasting hyperglycemia and IGT in the majority of patients. MODY2 may be misdiagnosed as type 1 diabetes in children, gestational diabetes in pregnant women, or well-controlled type 2 diabetes in adults (Table 589-17). An accurate diagnosis is important because most cases are not progressive, and except for gestational diabetes, may not require treatment. When needed, they can usually be treated with small doses of exogenously administered insulin. Treatment with oral agents (sulfonylureas and related drugs) can be successful and may be more acceptable to many patients.

**MODY3**

Patients affected with mutations in the transcription factor hepatocyte nuclear factor 1-α show abnormalities of carbohydrate metabolism varying from IGT to severe diabetes and often progressing from a mild to a severe form over time. They are also prone to the development of vascular complications. This is the most common MODY subtype and accounts for 50-65% of all cases. These patients are very sensitive to the action of sulfonylureas and can usually be treated with relatively low doses of these oral agents, at least in the early stages of the disease. In children, this form of MODY is sometimes misclassified as T1DM and treated with insulin. Evaluation of autoimmune markers will rule out T1DM, and genetic testing for this form of MODY is now available and is indicated in patients with relatively mild diabetes and a family history suggestive of autosomal dominant inheritance. On the other hand, even patients with relatively mild and gradual onset of diabetes may have T1DM, and in the absence of a family history suggestive of autosomal dominant inheritance, the diagnosis of MODY is not warranted. Accurate diagnosis can lead to avoidance of unnecessary insulin treatment and specific genetic counseling.

Hepatocyte nuclear factor 4-α (MODY1), insulin promoter factor (IPF)-1, also known as (PDX-1) (MODY4), hepatocyte nuclear factor 1-β (TCF2) (MODY5), and NeuroD1 (MODY6) are all transcription factors that are involved in β-cell development and function and mutations in these lead to various rare forms of MODY. In addition to diabetes they can also have specific findings unrelated to hyperglycemia; for example, MODY1 is associated with low triglyceride and lipoprotein levels and MODY5 is associated with renal cysts and renal dysfunction. In terms of treatment, MODY1 and MODY4 may respond to oral sulfonylureas, but MODY5 does not respond to oral agents and requires treatment with insulin. NeuroD1 defects are extremely rare and not much is known about their natural history.

Primary or secondary defects in the glucose transporter-2, which is an insulin-independent glucose transporter, may also be associated with diabetes. Diabetes may also be a manifestation of a polymorphism in the glycogen synthase gene. This enzyme is crucially important for storage of glucose as glycogen in muscle. Patients with this defect are notable for marked insulin resistance and hypertension, as well as a strong family history of diabetes.

**Mitochondrial Gene Defects**

Maternally Inherited Diabetes and Deafness. Point mutations in mitochondrial DNA are sometimes associated with maternally inherited DM and deafness. The most common mitochondrial DNA mutation in these cases is the point mutation m.3243A>G in the transfer RNA leucine gene. This mutation is identical to the
mutation in MELAS (myopathy, encephalopathy, lactic acidosis, and stroke-like syndrome), but this syndrome is not associated with diabetes; the phenotypic expression of the same defect varies. Diabetes in most of these cases presents insidiously but approximately 20% of patients have an acute presentation resembling T1DM. The mean age of diagnosis of diabetes is 37 yr but cases have been reported as young as 11 yr. This mutation has been estimated to be present in 1.5% of Japanese diabetics, which may be higher than the prevalence in other ethnic groups. Metformin should be avoided in these patients because of the theoretical risk of severe lactic acidosis in the presence of mitochondrial dysfunction.

Another form of IDDM, sometimes associated with mitochondrial mutations, is the Wolfram syndrome. Wolfram syndrome 1 is characterized by diabetes insipidus, DM, optic atrophy, and deafness—thus, the acronym DIDMOAD. Some patients with diabetes appear to have severe insulinopenia, whereas others have significant insulin secretion as judged by C-peptide. The overall prevalence is 1 in 770,000 live births. The sequence of appearance of the stigmata is as follows: non-autoimmune IDDM in the 1st decade, central diabetes insipidus and sensorineural deafness in two thirds to three fourths of the patients in the 2nd decade, renal tract anomalies in about one half of the patients in the 3rd decade, and neurologic complications such as cerebellar ataxia and myoclonus in one half to two thirds of the patients in the 4th decade. Other features include primary gonadal atrophy in the majority of males and a progressive neurodegenerative course with neurorespiratory death at a median age of 30 yr. Some (but not all) cases are caused by mutations in the WFS-1 (wolframin) gene on chromosome 4p. Wolfram syndrome 2 has early-onset optic atrophy, DM, deafness, and a shortened life span but no diabetes insipidus; the associated gene is CISD2.
DIABETES MELLITUS OF THE NEWBORN

Neonatal DM is exceedingly rare. Onset of classic autoimmune T1DM before the age of 6 mo is most unusual and most cases of diabetes in this age range are caused by genetic mutations.

Transient Neonatal Diabetes Mellitus

Neonatal diabetes is transient in approximately 50% of cases, but after an interim period of normal glucose tolerance, 50–60% of these patients develop permanent diabetes (at an average age of 14 yr). There are also reports of patients with classic T1DM who formerly had transient diabetes of the newborn. It remains to be determined whether this association of transient diabetes in the newborn followed much later in life by classic T1DM is a chance occurrence or causally related.

The syndrome of transient DM in the newborn infant has its onset in the 1st wk of life and persists several weeks to months before spontaneous resolution. Median duration is 12 wk. It occurs most often in infants who are small for gestational age and is characterized by hyperglycemia and pronounced glycosuria, resulting in severe dehydration and, at times, metabolic acidosis, but with only minimal or no ketonemia or ketonuria. There may also be findings such as umbilical hernia or large tongue. Insulin responses to glucose or tolbutamide are low to absent; basal plasma insulin concentrations are normal. After spontaneous recovery, the insulin responses to these same stimuli are brisk and normal, implying a functional delay in β-cell maturation with spontaneous resolution. Occurrence of the syndrome in consecutive siblings has been reported. About 70% of cases are due to abnormalities of an imprinted locus on chromosome 6q24, resulting in overexpression of paternally expressed genes such as pleomorphic adenoma gene-like 1 (PLAGL1/ZAC) and hydatidiform mole-associated and imprinted (HYMA1). Most of the remaining cases are caused by mutations in K_{ATP} channels. Mutations in K_{ATP} channels also cause many cases of permanent neonatal diabetes, but there is practically no overlap between the mutations that lead to transient neonatal DM and those causing permanent neonatal DM. This syndrome of transient neonatal DM should be distinguished from the severe hyperglycemia that may occur in hypertonic dehydration; that usually occurs in infants beyond the newborn period and responds promptly to hydration with minimal or no requirement for insulin.

Administration of insulin is mandatory during the active phase of DM in the newborn. One to 2 units/kg/24 hr of an intermediate-acting insulin in 2 divided doses usually results in dramatic improvement and accelerated growth and gain in weight. Attempts at gradually reducing the dose of insulin may be made as soon as recurrent hypoglycemia becomes manifested or after 2 mo of age. Genetic testing is now available for 6q24 abnormalities as well as potassium channel defects and should be obtained on all patients and recurrence risk assessment by a genetic counselor is recommended.

Permanent Neonatal Diabetes Mellitus

Permanent DM in the newborn period is caused in approximately 50% of the cases by mutations in the KCNJ11 (potassium inwardly-rectifying channel J, member 11) and ABCC8 (adenosine triphosphate–binding cassette, subfamily C, member 8) genes. These genes code for the Kir6.2 and SUR1 subunits of the adenosine triphosphate–sensitive potassium channel subunit Kir6.2) are associated with both transient neonatal DM and permanent neonatal DM, with particular mutations being associated with each phenotype. More than 90% of these patients respond to sulfonylureas (at higher doses than those used in T2DM), but patients with severe neurologic disease may be less responsive. Mutations in the ABCG8 gene (encoding the SUR1 subunit of this potassium channel) were thought to be less likely to respond to sulfonylureas (because this is the subunit that binds sulfonylurea drugs), but some of these mutations are reported to respond and patients have been successfully switched from insulin to oral therapy. Several protocols for switching the patient from insulin to glibenclamide are available and patients are usually stabilized on doses ranging from 0.4–1 mg/kg/day. Because approximately 50% of neonatal diabetics have K-channel mutations that can be switched to sulfonylurea therapy, with dramatic improvement in glycemic control and quality of life, all patients with diabetes diagnosed before 6 mo of age (and perhaps even those diagnosed before 12 mo of age) should now be screened for these mutations by genetic testing.

IPEX Syndrome

IPEX means immunodysregulation, polyendocrinopathy, and enteropathy, X-linked. In most patients with IPEX, mutations in the FOXP3 (forkhead box P3) gene, a specific marker of natural and adaptive regulatory T cells, leads to severe immune dysregulation and rampant autoimmunity. Autoimmune diabetes develops in >90% of cases, usually within the 1st few wk of life and is accompanied by enteropathy, failure to thrive, and other autoimmune disorders (see Chapter 126.5). Abnormalities of the Insulin Gene

Diabetes of variable degrees may also result from defects in the insulin gene that lead to various amino acid substitutions that impair the effectiveness of insulin at the receptor level. Insulin gene defects are exceedingly rare and may be associated with relatively mild diabetes or even normal glucose tolerance. Diabetes may also develop in patients with faulty processing of proinsulin to insulin (an autosomal dominant defect). These defects are notable for the high concentration of insulin as measured by radioimmunoassay, whereas MODY and glucose transporter-2 defects are characterized by relative or absolute deficiency of insulin secretion for the prevailing glucose concentrations.

GENETIC DEFECTS OF INSULIN ACTION

Various genetic mutations in the insulin receptor can impair the action of insulin at the insulin receptor or impair postreceptor signaling, leading to insulin resistance. The mildest form of the syndrome with mutations in the insulin receptor was previously known as type A insulin resistance. This is associated with hirsutism, hyperandrogenism, and cystic ovaries in females, without obesity. Acanthosis nigricans may be present and life expectancy is not significantly impaired. More-severe forms of insulin resistance are seen in 2 mutations in the insulin receptor gene that cause the pediatric syndromes of Donohue syndrome (formerly called leprechaunism) and Rabson-Mendenhall syndrome.

Donohue Syndrome

This is a syndrome characterized by intrauterine growth restriction, fasting hypoglycemia, and postprandial hyperglycemia in association with profound resistance to insulin; severe hyperinsulinemia is seen compared to age-matched infants during an oral glucose tolerance test. Various defects of the insulin receptor have been described, thereby attesting to the important role of insulin and its receptor in fetal growth and possibly in morphogenesis. Most of these patients die in the 1st yr of life.

Rabson-Mendenhall Syndrome

This entity is defined by clinical manifestations that appear to be intermediate between those of acanthosis nigricans with insulin resistance type A and Donohue syndrome. The features include extreme insulin
resistance, acanthosis nigricans, abnormalities of the teeth and nails, and pineal hyperplasia. It is not clear whether this syndrome is entirely distinct from Donohue syndrome; however, by comparison, patients with Rabson-Mendenhall tend to live significantly longer. Therapies with modest benefit have included insulin-like growth factor-1 and leptin.

**Lipoatrophic Diabetes**

Various forms of lipodystrophy are associated with insulin resistance and diabetes (Table 589-18). Familial partial lipodystrophy is associated with mutations in the LMNA gene, encoding nuclear envelope proteins lamin A and C. Severe generalized lipodystrophy is associated with mutations in the AGPAT2 genes, but the mechanism by which these mutations lead to insulin resistance and diabetes is not known.

**Stiff-Person Syndrome**

This is an extremely rare autoimmune central nervous system disorder that is characterized by progressive stiffness and painful spasms of the axial muscles and very high titers of glutamic acid decarboxylase antibodies. About one third of the patients also develop T1DM.

**Systemic Lupus Erythematosus**

In rare cases, patients with systemic lupus erythematosus may develop autoantibodies to the insulin receptor, leading to insulin resistance and diabetes.

**CYSTIC FIBROSIS–RELATED DIABETES**

See Chapter 403.

As patients with cystic fibrosis (CF) live longer, an increasing number are being diagnosed with cystic fibrosis–related diabetes (CFRD). Females appear to have a somewhat higher risk of CFRD than males and prevalence increases with increasing age until age 40 yr (there is a decline in prevalence after that, presumably because only the healthiest CF patients survive beyond that age). There is an association with pancreatic insufficiency and there may be a higher risk in patients with class I and class II CF transmembrane conductance regulator mutations. A large multicenter study in the United States reported prevalence (in all ages) of 17% in females and 12% in males. Cross-sectional studies indicate that the prevalence of IGT may be significantly higher than this and up to 65% of children with CF have diminished 1st phase insulin secretion, even when they have normal glucose tolerance. In Denmark, oral glucose tolerance screening of the entire CF population demonstrated no diabetes in patients younger than 10 yr, diabetes in 12% of patients age 10-19 yr, and diabetes in 48% of adults age 20 yr and older. A Midwest center where routine annual oral glucose tolerance screening is performed, only about one half of children and one fourth of adults have normal glucose tolerance.

Patients with CFRD have features of both T1DM and T2DM. In the pancreas, exocrine tissue is replaced by fibrosis and fat and many of the pancreatic islets are destroyed. The remaining islets demonstrate diminished numbers of β-, α-, and pancreatic polypeptide-secreting cells. Secretion of the islet hormones insulin, glucagon, and pancreatic polypeptide is impaired in patients with CF in response to a variety of secretagogues. This pancreatic damage leads to slowly progressive insulin deficiency, of which the earliest manifestation is an impaired 1st phase insulin response. As patients age, this response becomes progressively delayed and less robust than normal. At the same time, these patients develop insulin resistance due to chronic inflammation and the intermittent use of corticosteroids. Insulin deficiency and insulin resistance lead to a very gradual onset of IGT that eventually evolves into diabetes. In some cases, diabetes may wax and wane with disease exacerbations and the use of corticosteroids. The clinical presentation is similar to that of T2DM in that the onset of the disease is insidious and the occurrence of ketoacidosis is rare. Islet antibody titers are negative. Microvascular complications do develop but may do so at a slower rate than in typical T1DM or T2DM. Macrovascular complications do not appear to be of concern in CFRD, perhaps because of the shortened

life span of these patients. Several factors unique to CF influence the onset and the course of diabetes. For example: (1) frequent infections are associated with waxy and waning of insulin resistance; (2) energy needs are increased because of infection and pulmonary disease; (3) malabsorption is common, despite enzyme supplementation; (4) nutrient absorption is altered by abnormal intestinal transit time; (5) liver disease is frequently present; (6) anorexia and nausea are common; (7) there is a wide variation in daily food intake based on the patient’s acute health status; and (8) both insulin and glucagon secretion are impaired (in contrast to autoimmune diabetes, in which only insulin secretion is affected).

Impaired glucose tolerance and CFRD are associated with poor weight gain and there is evidence that treatment with insulin improves weight gain and slows the rate of pulmonary deterioration. Because of these observations, the CF Foundation recommends routine diabetes screening of all children with CF, starting at age 12 yr. Despite debate over the ideal screening modality, the current recommendation is the 2 hr glucose tolerance test, though it is possible that simply obtaining a single 2 hr postprandial glucose value may be sufficient. When hyperglycemia develops, the accompanying metabolic derangements are usually mild, and relatively low doses of insulin usually suffice for adequate management. Basal insulin may be started initially, but basal-bolus therapy similar to that used in T1DM will eventually be needed. Dietary restrictions are minimal as increased energy needs are present and weight gain is usually desired. Ketaocidosis is very uncommon but may occur with progressive deterioration of islet cell function. Impaired glucose tolerance is not necessarily an indication for treatment, but patients who have poor growth and inadequate weight gain may benefit from the addition of basal insulin even if they do not meet the criteria for diagnosis of diabetes.

AUTOIMMUNE DISEASES

Chronic lymphocytic thyroiditis (Hashimoto thyroiditis) is frequently associated with T1DM in children (see Chapter 566). As many as 1 in 5 insulin-dependent diabetic patients have thyroid antibodies in their serum; the prevalence is 2-20 times greater than in control populations. Only a small proportion of these patients, however, acquire clinical hypothyroidism; the interval between diagnosis of diabetes and thyroid disease averages about 5 yr. Periodic palpation of the thyroid gland is indicated in all diabetic children; if the gland feels firm or enlarged, serum measurements of thyroid antibodies and TSH should be obtained. A confirmed TSH level of greater than 10 µU/mL indicates existing or incipient thyroid dysfunction that warrants replacement with thyroid hormone. Deceleration in the rate of growth may also be caused by thyroid failure and is, in itself, a reason for securing serum measurements of thyroxine and TSH concentrations.

When diabetes and thyroid disease coexist, the possibility of autoimmune adrenal insufficiency should be considered. It may be heralded by decreasing insulin requirements, increasing pigmentation of the skin and buccal mucosa, salt craving, weakness, asthenia and postural hypotension, or even frank Addisonian crisis. This syndrome is most unusual in the 1st decade of life, but it may become apparent in the 2nd decade or later.

Celiac disease, which is caused by hypersensitivity to dietary gluten, is another autoimmune disorder that occurs with significant frequency in children with T1DM (see Chapter 338.2). It is estimated that approximately 7-15% of children with T1DM develop celiac disease within the 1st 6 yr of diagnosis, and the incidence of celiac disease is significantly higher in children younger than 4 yr of age and in girls. Young children with T1DM and celiac disease usually present with gastrointestinal symptoms (abdominal cramping, diarrhea, and gastrointestinal reflux), growth failure as a consequence of suboptimal weight gain, and unexplained hypoglycemic reactions because of nutrient malabsorption, including vitamin D; adolescents may remain asymptomatic. The diagnosis of celiac disease is considered if serum tissue transglutaminase antibody titers are elevated in the presence of normal serum total IgA levels. The diagnosis is confirmed on endoscopic evaluation and biopsy of small bowel revealing characteristic atrophy of intestinal villi. Therapy consists of a gluten-free diet, which will alleviate gastrointestinal symptoms and may reduce glycemic excursions.

Circulating antibodies to gastric parietal cells and to intrinsic factor are 2-3 times more common in patients with T1DM than in control subjects. The presence of antibodies to gastric parietal cells is correlated with atrophic gastritis and antibodies to intrinsic factor are associated with malabsorption of vitamin B12. However, megaloblastic anemia is rare in children with T1DM.

A variant of the multiple endocrine deficiency syndrome is characterized by T1DM, idiopathic intestinal mucosal atrophy with associated inflammation and severe malabsorption, IgA deficiency, and circulating antibodies to multiple endocrine organs including the thyroid, adrenal, pancreas, parathyroid, and gonads. In addition, non-diabetic family members have an increased frequency of vitiligo, Graves disease, and multiple sclerosis as well as low complement levels and antibodies to endocrine tissues.

ENDOCRINOPATHIES

The endocrinopathies listed in Table 589-1 are only rarely encountered as a cause of diabetes in childhood. They may accelerate the manifestations of diabetes in those with inherited or acquired defects in insulin secretion or action.

DRUGS

High-dose oral or parenteral steroid therapy usually results in significant insulin resistance leading to glucose intolerance and overt diabetes. The immunosuppressive agents cyclosporin and tacrolimus are toxic to β cells, causing IDDM in a significant proportion of patients treated with these agents. Their toxicity to pancreatic β cells was 1 of the factors that limited their usefulness in arresting ongoing autoimmune destruction of β cells. Streptozotocin and the rodenticide Vacor are also toxic to β cells, causing diabetes.

There are no consensus guidelines regarding treatment of steroid-induced hyperglycemia in children. Many patients on high-dose steroids have elevated blood glucose during the day and evening, but become normoglycemic late at night and early in the morning. In general, significant hyperglycemia in an inpatient setting is treated with short-acting insulin on an as-needed basis. Basal insulin may be added when fasting hyperglycemia is significant. Outpatient treatment can be more difficult, but when treatment is needed, protocols similar to the basal-bolus regimens used in T1DM are used.

GENETIC SYNDROMES ASSOCIATED WITH DIABETES MELLITUS

A number of rare genetic syndromes associated with IDDM or carbohydrate intolerance have been described (see Table 589-1). These syndromes represent a broad spectrum of diseases, ranging from premature cellular aging, as in the Werner and Cockayne syndromes (see Chapter 90) to excessive obesity associated with hyperinsulaemia, resistance to insulin action, and carbohydrate intolerance, as in the Prader-Willi syndrome (see Chapters 80 and 81). Some of these syndromes are characterized by primary disturbances in the insulin receptor or in antibodies to the insulin receptor without any impairment in insulin secretion. Although rare, these syndromes provide unique models to understand the multiple causes of disturbed carbohydrate metabolism from defective insulin secretion or from defective insulin action at the cell receptor or postreceptor level.

**Long-Term Outcome of Childhood Diabetes: Relation of Control to Development of Complications**

**Type 2 Diabetes and Diseases and Syndromes Associated with Diabetes**

Historical markers of neurologic dysfunction include full-term infants who are unable to breathe spontaneously; have poor, uncoordinated sucks; need an inordinate amount of time to feed; or require gavage feeding. Again, it is important to consider the developmental context, because all of these issues would be expected in premature infants, particularly those with a very-low birthweight. Double-checking the state newborn screening results may provide a clue to abnormal neurologic manifestation in an infant.

The most important component of a neurologic history is the developmental assessment (see Chapters 9–14 and 16). Careful evaluation of a child’s social, cognitive, language, fine motor, and gross motor skills is required to distinguish normal development from either isolated or global (i.e., in 2 or more domains) developmental delay. An abnormality in development from birth suggests an intrauterine or perinatal cause, but a loss of skills (regression) over time strongly suggests an underlying degenerative disease of the CNS, such as an inborn error of metabolism. The ability of parents to recall the precise timing of their child’s developmental milestones is extremely variable. It is often helpful to request old photographs of the child or to review the baby book, where the milestones may have been dutifully recorded. In general, parents are aware when their child has a developmental problem, and the physician should show appropriate concern. Table 590–1 outlines the upper limits of normal for attaining specific developmental milestones. Chapter 16 includes a comprehensive review of developmental screening tests and their interpretation.

Family history is extremely important in the neurologic evaluation of a child. Most parents are extremely cooperative in securing medical information about family members, particularly if it might have relevance for their child. The history should document the age and history of neurologic disease, including developmental delay, epilepsy, migraine, stroke, and inherited disorders, for all 1st- and 2nd-degree relatives. It is important to inquire directly about miscarriages or fetal deaths in utero and to document the sex of the embryo or fetus, as well as the gestational age at the time of demise. When available, the results of postmortem examinations should be obtained, as they can have a direct bearing on the patient’s condition. The parents should be questioned about their ethnic backgrounds, because some genetic disorders occur more commonly within specific populations (e.g., Tay-Sachs disease in the Ashkenazi Jewish population). They should also be asked if there is any chance that they could be related to each other, because the incidence of metabolic and degenerative disorders of the CNS is increased significantly in children of consanguineous marriages.

The social history should detail the child’s current living environment, as well as the child’s relationship with other family members. It is important to inquire about recent stressors, such as divorce, remarriage, birth of a sibling, or death of a loved one, because they can affect the child’s behavior. If the child is in daycare or school, one should document the child’s academic and social performance, paying particular attention to any abrupt changes. Academic performance can be assessed by asking about the child’s latest report card, and peer relationships can be evaluated by having the child name his or her “best friends.” Any child who is unable to name at least 2 or 3 playmates might have abnormal social development. In some cases, discussions with the daycare worker or teacher provide useful ancillary data.

NEUROLOGIC EXAMINATION
The neurologic examination begins at the outset of the interview. Indirect observation of the child’s appearance and movements can yield valuable information about the presence of an underlying disorder. For instance, it may be obvious that the child has dysmorphic facies, an
unusual posture, or an abnormality of motor function manifested by a hemiparesis or gait disturbance. The child's behavior while playing and interacting with his or her parents may also be telling. A normal child usually plays independently early in the visit, but then engages in the interview process. A child with attention-deficit/hyperactivity disorder might display impulsive behavior in the examining room, and a child with neurologic impairment might exhibit complete lack of awareness of the environment. Finally, note should be made of any unusual odors about the patient, because some metabolic disorders produce characteristic scents (e.g., the “musty” smell of phenylketonuria or the “sweaty feet” smell of isovaleric acidemia). If such an odor is present, it is important to determine whether it is persistent or transient, occurring only with illnesses.

The examination should be conducted in a nonthreatening, child-friendly setting. The child should be allowed to sit where the child is most comfortable, whether it be on a parent's lap or on the floor of the examination room. The physician should approach the child slowly, reserving any invasive or painful tests (e.g., measurement of head circumference, gag reflex) for the end of the examination. In the end, the more that the examination seems like a game, the more the child will cooperate. Because the neurologic examination of an infant requires a somewhat modified approach from that of an older child, the 2 groups are considered separately (see Chapters 9, 10, and 94 vs Chapters 11-14).

### Mental Status

Age aside, the neurologic examination should include an assessment of the patient's mental status in terms of both level of arousal and interaction with the environment. Premature infants born at <28 wk of gestation do not have consistent periods of alertness, whereas slightly older infants arouse from sleep with gentle physical stimulation. Sleep–wake patterns are well developed at term. Because the level of alertness of a neonate depends on many factors, including the time of the last feeding, room temperature, and gestational age, serial examinations are critical when evaluating for changes in neurologic function. Older children's mental status can be assessed by watching them play. Having them tell a story, draw a picture, or complete a puzzle can also be helpful in assessing cognitive function. Memory can be evaluated informally as patients recount their personal information, as well as more formally by asking them to register and recall 3 objects or perform a digit span.

### Head

Correct measurement of the head circumference is important. It should be performed at every visit for patients younger than 3 yr and should be recorded on a suitable head growth chart. To measure, a nondistensible plastic measuring tape is placed over the mid-forehead and extended circumferentially to include the most prominent portion of the occiput. If the patient's head circumference is abnormal, it is important to document the head circumferences of the parents and siblings. Errors in the measurement of a newborn skull are common owing to scalp edema, overriding sutures, and the presence of cephalohematomas. The average rate of head growth in a healthy premature infant is 0.5 cm in the 1st 2 wk, 0.75 cm in the 3rd wk, and 1.0 cm in the 4th wk and every week thereafter until the 40th wk of development. The head circumference of an average term infant measures 34-35 cm at birth, 44 cm at 6 mo, and 47 cm at 1 yr of age (see Chapters 9 and 10).

If the brain is not growing, the skull will not grow; therefore, a small head frequently reflects a small brain, or microcephaly. Conversely, a large head may be associated with a large brain, or macrocephaly, which is most commonly familial but may be from a disturbance of growth, neurocutaneous disorder (e.g., neurofibromatosis), chromosomal defect (e.g., Klinefelter syndrome), or storage disorder. Alternatively, the head size may be increased secondary to hydrocephalus (Fig. 590-1) or chronic subdural hemorrhages. In the latter case, the skull tends to assume a square or box-like shape, because the long-standing presence of fluid in the subdural space causes enlargement of the middle fossa.

The shape of the head should be documented carefully. Plagiocephaly, or flattening of the skull, can be seen in normal infants but may be particularly prominent in hypotonic or weak infants, who are less mobile. A variety of abnormal head shapes can be seen when cranial sutures fuse prematurely, as in the various forms of inherited craniosynostosis (see Chapter 591.12).

An infant has 2 fontanels at birth: a diamond-shaped anterior fontanel at the junction of the frontal and parietal bones that is open at birth, and a triangular posterior fontanel at the junction of the parietal and occipital bones that can admit the tip of a finger or may be closed at birth. If the posterior fontanel is open at birth, it should close over the ensuing 6-8 wk; its persistence suggests underlying hydrocephalus or congenital hypothyroidism. The anterior fontanel varies greatly in size, but it usually measures approximately 2 × 2 cm. The average time of closure is 18 mo, but the fontanel can close normally as early as 9 mo. A very small or absent anterior fontanel at birth might indicate craniosynostosis or microcephaly, whereas a very large fontanel can

![Figure 590-1 Congenital hydrocephalus. Note the enlarged cranium and prominent scalp veins.](image-url)
signify a variety of problems. The fontanel is normally slightly depressed and pulsatile and is best evaluated by holding the infant upright while the infant is asleep or feeding. A bulging fontanel is a potential indicator of increased ICP, but vigorous crying can cause a protuberant fontanel in a normal infant.

Inspection of the head should include observation of the venous pattern, because increased ICP and thrombosis of the superior sagittal sinus can produce marked venous distention. Dysmorphic facial features can indicate a neurodevelopmental aberration. Likewise, cutaneous abnormalities, such as cutis aplasia or abnormal hair whorls, can suggest an underlying brain malformation or genetic disorder.

Palpation of a newborn’s skull characteristically reveals molding of the skull accompanied by overriding sutures—a result of the pressures exerted on the skull during its descent through the pelvis. Marked overriding of the sutures beyond the early neonatal period is cause for alarm, because it suggests an underlying brain abnormality. Palpation additionally might reveal bony bridges between sutures (craniosynostosis), cranial defects, or, in premature infants, softening of the parietal bones (craniotabes).

Auscultation of the skull is an important adjunct to the neurologic examination. Cranial bruits may be noted over the anterior fontanel, temporal region, or orbits, and are best heard using the diaphragm of the stethoscope. Soft symmetric bruits may be discovered in normal children younger than 4 yr of age or in association with a febrile illness. Demonstration of a loud or localized bruit is usually significant and warrants further investigation, because they may be associated with severe anemia, increased ICP, or arteriovenous malformations of the middle cerebral artery or vein of Galen. It is important to exclude murmurs arising from the heart or great vessels, because they may be transmitted to the cranium.

Cranial Nerves

Olfactory Nerve (Cranial Nerve I)

Anosmia, loss of smell, most commonly occurs as a transient abnormality in association with an upper respiratory tract infection or allergies. Permanent causes of anosmia include head trauma with damage to the ethmoid bone or shearing of the olfactory nerve fibers as they cross the cribiform plate, tumors of the frontal lobe, intranasal drug use, and exposure to toxins (acrylates, methacrylates, cadmium). Occasionally, a child who recovers from purulent meningitis or develops hydrocephalus has a diminished sense of smell. Rarely, anosmia is congenital, in which case it can occur as an isolated deficit or as part of Kallmann syndrome, a familial disorder characterized by hypogonadotropic hypogonadism and congenital anosmia. Although not a routine component of the examination, smell can be tested reliably as early as the 32nd wk of gestation by presenting a stimulus and observing for an alerting response, withdrawal, or both. Care should be taken to use appropriate stimuli, such as coffee or peppermint, as opposed to strongly aromatic substances (e.g., ammonia inhalants) that stimulate the trigeminal nerve. Each nostril should be tested individually by pinching shut the opposite side.

Optic Nerve (Cranial Nerve II)

Assessment of the optic disc and retina is a critical component of the neurologic examination. Although the retina is best visualized by dilating the pupil, most physicians do not have ready access to mydriatic agents at the bedside; therefore, it may be necessary to consult an ophthalmologist in some cases. Mydriatics should not be administered to patients whose pupillary responses are being followed as a marker for impending herniation or to patients with cataracts. When mydriatics are used, both eyes should be dilated, because unilateral papillary fixation and dilation can cause confusion and worry in later examiners unaware of the pharmacologic intervention. Examination of an infant’s retina may be facilitated by providing a nipple or soother and by turning the head to one side. The physician gently stokes the patient to maintain arousal, while examining the closer eye. An older child should be placed in the parent’s lap and should be distracted by bright objects or toys. The color of the optic nerve is salmon-pink in a child but may be gray-white in a newborn, particularly if the newborn has fair coloring. This normal finding can cause confusion and can lead to the improper diagnosis of optic atrophy.

Disc edema refers to swelling of the optic disc, and papilledema specifically refers to swelling that is secondary to increased ICP. Papilledema rarely occurs in infancy because the skull sutures can separate to accommodate the expanding brain. In older children, papilledema may be graded according to the Frisen scale (Fig. 590-2). Disc edema must be differentiated from papillitis, or inflammation of the optic nerve. Both conditions manifest with enlargement of the blind spot, but visual acuity and color vision tend to be spared in early papilledema in contrast to what occurs in optic neuritis.

Retinal hemorrhages occur in 30–40% of all full-term newborns. The hemorrhages are more common after vaginal delivery than after Cesarean section and are not associated with birth injury or with neurologic complications. They disappear spontaneously by 1–2 wk of age. The presence of retinal hemorrhages beyond the early neonatal period should raise a concern for nonaccidental trauma.

Vision

At 28 wk of corrected gestational age, a premature infant blinks in response to a bright light, and at 32 wk, the infant maintains eye closure until the light source is removed. A normal 37 wk infant turns the head and eyes toward a soft light, and a term infant is able to fix on and follow a target, such as the examiner’s face. Optokinetic nystagmus (OKN), which is conjugate nystagmus that occurs during attempted fixation on a series of rapidly moving objects, can also be used as a crude assessment of the visual system in infants. OKN is elicited by moving an OKN tape—usually a strip of material with alternating 2-inch black and white strips—across the patient’s visual field. Although OKN responses can be tested monocularly in neonates, they do not become symmetric until 4–6 mo of age.

Visual fields can be tested in an infant or young child by advancing a brightly colored object from behind the patient’s head into the peripheral visual field and noting when the patient first looks at the object. Suspension of the object by a string prevents the patient from focusing on the examiner’s hand and arm. The examiner should be certain that the patient is responding to seeing, not hearing, the object.

Visual acuity in term infants approaches 20/150 and reaches the adult level of 20/20 by about 6 mo of age. Children who are too young to read the standard letters on a Snellen eye chart may learn the “E” game,” which entails pointing to indicate the direction that the E is facing. Children as young as 2.5–3 yr of age can identify the objects on a pediatric eye chart (Allen chart) at a distance of 15–20 ft.

The pupil reacts to light by 29–32 wk of corrected gestational age; however, the pupillary response is often difficult to evaluate, because premature infants resist eye opening and have poorly pigmented irises. Pupillary size, symmetry, and reactivity may be affected by drugs, space-occupying brain lesions, metabolic disorders, and abnormalities of the optic nerves and midbrain. A small pupil may be seen as part of the Horner syndrome—characterized by ipsilateral ptosis (droopy eyelid), miosis (constricted pupil), and anhidrosis (lack of sweating) of the face. Horner syndrome may be congenital or may be caused by a lesion of the sympathetic pathway in the hypothalamus, brainstem, cervical spinal cord, or sympathetic plexus. Localization of the lesion within the sympathetic nervous system may be obvious given the other signs present or may be uncertain. In the latter case, serial testing with cocaine drops followed by hydroxyamphetamine drops may be helpful.

During the examination of the pupil, any abnormalities of the iris should also be noted (e.g., heterochromia, Brushfield spots). The physician should also assess the posterior segment of the eye using the red reflex test, which is performed in a darkened room using a direct ophthalmoscope held close to the examiner’s eye and 12–18 inches from the infant’s eyes. If the posterior segment of the eye is normal, the examiner should see symmetric reddish-pink retinal reflections. The absence of any red reflex or the presence of a blunted reflex, white reflex (leukocoria), or red reflex with dark spots all signal pathology and should prompt referral to an ophthalmologist.
Oculomotor (Cranial Nerve III), Trochlear (Cranial Nerve IV), and Abducens Nerves (Cranial Nerve VI)

The globe is moved by 6 extraocular muscles, which are innervated by the oculomotor, trochlear, and abducens nerves. These muscles and nerves can be assessed by having the patient follow an interesting toy or the examiner's finger in the 6 cardinal directions of gaze. The physician observes the range and nature (conjugate vs dysconjugate, smooth vs choppy or saccadic) of the eye movements, particularly noting the presence and direction of any abnormal eye movements. Premature infants older than 25 wk of gestational age and comatose patients can have slightly disconjugate gaze at rest, with 1 eye deviating slightly beyond the midline. Patients with increased ICP often respond positively when questioned about double vision (diplopia) and exhibit incomplete abduction of the eyes on lateral gaze as a result of partial VIth nerve palsies. This false-localizing sign occurs because CN VI has a long intracranial course, making it particularly susceptible to being stretched. Internuclear ophthalmoplegia, caused by a lesion in the medial longitudinal fasciculus of the brainstem, that functionally serves conjugate gaze by connecting CN VI on one side to CN III on the other, results in paralysis of medial rectus function in the adducting eye and nystagmus in the abducting eye.

When there is a subtle eye movement abnormality, the red glass test may be helpful in localizing the lesion. To perform this test, a red glass is placed over one of the patient's eyes and the patient is instructed to follow a white light in all directions of gaze. The child sees 1 red/white light in the direction of normal muscle function but notes a separation of the red and white images that is greatest in the plane of action of the affected muscle.

In addition to gaze palsies, the examiner might encounter a variety of adventitious movements. Nystagmus is an involuntary, rapid movement of the eye that may be subclassified as being pendular, in which the 2 phases have equal amplitude and velocity, or jerk, in which there is a fast and slow phase. Jerk nystagmus can be further characterized by the direction of its fast phase, which may be left-, right-, up-, or downbeating; rotatory; or mixed. Many patients have a few beats of nystagmus with extreme lateral gaze (end-gaze nystagmus), which is

![Figure 590-2 Stages of papilledema (Frisen scale).](image)

(A-C courtesy Dr. Deborah Friedman; D-F courtesy Flaum Eye Institute, University of Rochester.)

Stage 0: Normal optic disc. B, Stage 1: Very early papilledema with obscuration of the nasal border of the disc only, without elevation of the disc borders. C, Stage 2: Early papilledema showing obscuration of all borders, elevation of the nasal border, and a complete peripapillary halo. D, Stage 3: Moderate papilledema with elevation of all borders, increased diameter of the optic nerve head, obscuration of vessels at the disc margin, and a peripapillary halo with finger-like extensions. E, Stage 4: Marked papilledema characterized by elevation of the entire nerve head and total obscuration a segment of a major blood vessel on the disc. F, Stage 5: Severe papilledema with obscuration of all vessels and obliteration of the optic cup. Note also the nerve fiber layer hemorrhages and macular exudate.
of no consequence. Pathologic horizontal nystagmus is most often congenital, drug-induced (e.g., alcohol, anticonvulsants), or a result of vestibular system dysfunction. By contrast, vertical nystagmus is often associated with structural abnormalities of the brainstem and cerebellum. **Ocular bobbing** is characterized by a downward jerk followed by a slow drift back to primary position and is associated with pontine lesions. **Opsoclonus** describes involuntary, chaotic oscillations of the eyes, which are often seen in the setting of neuroblastoma or viral infection.

**Trigeminal Nerve (Cranial Nerve V)**
The 3 divisions of the trigeminal nerve—ophthalmic, maxillary, and mandibular—convey information about facial protopathic (pain, temperature) and epicritic (vibration, proprioception) sensation. Each modality should be tested and compared to the contralateral side. In patients who are uncooperative or comatose, the integrity of the trigeminal nerve can be assessed by the corneal reflex, elicited by touching the cornea with a small pledget of cotton and observing for symmetric eye closure, and nasal tickle, obtained by stimulating the nasal passage with a cotton swab and observing for symmetric grimace. An absent reflex may be because of a sensory defect (trigeminal nerve) or a motor deficit (facial nerve). The motor division of the trigeminal nerve can be tested by examining the masseter, pterygoid, and temporalis muscles during mastication, as well as by evaluation of the jaw jerk.

**Facial Nerve (Cranial Nerve VII)**
The facial nerve is a predominantly motor nerve that innervates the muscles of facial expression, buccinator; platysma, stapedius, stylohyoid, and posterior belly of the digastric. It also has a separate division, called the chorda tympani, that contains sensory, special sensory (taste), and parasympathetic fibers. Because the portion of the facial nucleus that innervates the upper face receives bilateral cortical input, lesions of the motor cortex or corticobulbar tract have little effect on upper face strength. Rather, such lesions manifest with flattening of the contralateral nasolabial fold or drooping of the corner of the mouth. Conversely, lower motor neuron or facial nerve lesions tend to involve upper and lower facial muscles equally. Facial strength can be evaluated by observing the patient's spontaneous movements and by asking the patient to mimic a series of facial movements (e.g., smiling, raising the eyebrows, inflating the cheeks). A facial nerve palsy may be congenital; idiopathic (**Bell palsy**); or secondary to trauma, demyelination (**Guillain-Barré syndrome**), infection (**Lyme disease**, herpes simplex virus, HIV), granulomatous disease, neoplasm, or meningeal inflammation or infiltration. Facial nerve lesions that are proximal to the junction with the chorda tympani will result in an inability to taste substances with the anterior two-thirds of the tongue. If necessary, taste can be tested by placing a solution of saline or glucose on 1 side of the extended tongue. Normal children can identify the test substance in <10 sec. Other findings that may be associated with facial nerve palsy include hyperacusis, resulting from stapedius muscle involvement, and impaired tearing.

**Vestibulocochlear Nerve (Cranial Nerve VIII)**
The vestibulocochlear nerve has 2 components within a single trunk: the vestibular nerve, which innervates the semicircular canals of the inner ear and is involved with equilibrium, coordination, and orientation in space, and the cochlear nerve, which innervates the cochlea and subserves hearing.

Dysfunction of the vestibular system results in vertigo, the sensation of environmental motion. On examination, patients with vestibular nerve dysfunction typically have nystagmus, in which the fast component is directed away from the affected nerve. With their arms outstretched and eyes closed, their limbs tend to drift toward the injured side. Likewise, if they march in place, they slowly pivot toward the lesion (**Fukuda stepping test**). On Romberg and tandem gait testing, they tend to fall toward the abnormal ear. Vestibular function can be further evaluated with **caloric testing**. Before testing, the tympanic membrane should be visualized to ensure that it is intact and unobstructed. In an obtunded or comatose patient, 30-50 mL of ice water is then delivered by syringe into the external auditory canal with the patient's head elevated 30 degrees. If the brainstem is intact, the eyes deviate toward the irrigated side. A much smaller quantity of ice water (2 mL) is used in awake, alert patients to avoid inducing nausea. In normal subjects, introduction of ice water produces eye deviation toward the stimulated labyrinth followed by nystagmus with the fast component away from the stimulated labyrinth.

Because hearing is integral to normal language development, the physician should inquire directly about hearing problems. **Parent's concern** is often a reliable indicator of hearing impairment and warrants a formal audiologic assessment with either audiometry or brainstem auditory evoked potential testing (see Chapter 637). Even in the absence of parents’ concern, certain children warrant formal testing within the 1st mo of life, including those with a family history of early life or syndromic deafness or a personal history of prematurity, severe asphyxia, exposure to ototoxic drugs, hyperbilirubinemia, congenital anomalies of the head or neck, bacterial meningitis, and congenital TORCH (toxoplasmosis, other infections, rubella, cytomegalovirus, herpes simplex virus) infections. For all other infants and children, a simple bedside assessment of hearing is usually sufficient. Newborns might have subtle responses to auditory stimuli, such as changes in breathing, cessation of movement, or opening of the eyes and/or mouth. If the same stimulus is presented repeatedly, normal neonates cease to respond, a phenomenon known as **habituation**. By 3-4 mo of age, infants begin to orient to the source of sound. Hearing-impaired toddlers are visually alert and appropriately responsive to physical stimuli but might have more frequent temper tantrums and abnormal speech and language development.

**Glossopharyngeal Nerve (Cranial Nerve IX)**
The glossopharyngeal nerve conveys motor fibers to the stylopharyngeus; general sensory fibers from the posterior third of the tongue, pharynx, tonsil, external surface of the tympanic membrane, and skin of the external ear; special sensory (taste) fibers from the posterior third of the tongue; parasympathetic fibers to the parotid gland; and general visceral sensory fibers from the carotid bodies. The nerve is tested by stimulating 1 side of the lateral oropharynx or soft palate with a tongue blade and observing for symmetric elevation of the palate (**gag reflex**). An isolated lesion of CN IX is rare, because it runs in close proximity to CN X. Potential causes of injury and/or dysfunction include birth trauma, ischemia, mass lesions, motor neuron disease, retropharyngeal abscess, and Guillain-Barré syndrome.

**Vagus Nerve (Cranial Nerve X)**
The vagus nerve has 10 terminal branches: meningeal, auricular, pharyngeal, carotid body, superior laryngeal, recurrent laryngeal, cardiac, pulmonary, esophageal, and gastrointestinal. The pharyngeal, superior laryngeal, and recurrent laryngeal branches contain motor fibers that innervate all of the muscles of the pharynx and larynx, with the exception of the stylopharyngeus (CN IX) and tensor veli palatini (CN V) muscles. Thus, unilateral injury of the vagus nerve results in weakness of the ipsilateral soft palate and a hoarse voice; bilateral lesions can produce respiratory distress as a result of vocal cord paralysis, as well as nasal regurgitation of fluids, pooling of secretions, and an immobile, low-lying soft palate. Isolated lesions to the vagus nerve may be a complication of thoracotomies or may be seen in neonates with type II Chiari malformations. If such a lesion is suspected, it is important to visualize the vocal cords. In addition to motor information, the vagus nerve carries somatic afferents from the pharynx, larynx, ear canal, external surface of the tympanic membrane, and meninges of the posterior fossa; visceral afferents; taste fibers from the posterior pharynx; and preganglionic parasympathetics.

**Accessory Nerve (Cranial Nerve XI)**
The accessory nerve innervates the sternocleidomastoid (SCM) and trapezius muscles. The left SCM acts to turn the head to the right side and vice versa; acting together, the SCMs flex the neck. The trapezius
acts to elevate the shoulder. Lesions to the accessory nerve result in atrophy and paralysis of the ipsilateral SCM and trapezius muscles, with resultant depression of the shoulder. Because several cervical muscles are involved in head rotation, unilateral SCM paresis might not be evident unless the patient is asked to rotate the head against resistance. Skull base fractures or lesions, motor neuron disease, myotonic dystrophy, and myasthenia gravis commonly produce atrophy and weakness of these muscles; congenital torticollis is associated with SCM hypertrophy.

**Hypoglossal Nerve (Cranial Nerve XII)**

The hypoglossal nerve innervates the tongue. Examination of the tongue includes assessment of its bulk and strength, as well as observation for adventitious movements. Malfunction of the hypoglossal nucleus or nerve produces atrophy, weakness, and fasciculations of the tongue. If the injury is unilateral, the tongue deviates toward the side of the injury; if it is bilateral, tongue protrusion is not possible and the patient can have difficulty swallowing (dysphagia). Werdnig-Hoffmann disease (infantile spinal muscular atrophy, or spinal muscular atrophy type 1) and congenital anomalies in the region of the foramen magnum are the principal causes of hypoglossal nerve dysfunction.

**Motor Examination**

The motor examination includes assessment of muscle bulk, tone, and strength, as well as observation for involuntary movements that might indicate central or peripheral nervous system pathology.

**Bulk**

Decreased muscle bulk (atrophy) may be secondary to disuse or to diseases of the lower motor neuron, nerve root, peripheral nerve, or muscle. In most cases, neurogenic atrophy is more severe than myogenic atrophy. Increased muscle bulk (hypertrophy) is usually physiologic (e.g., body builders). Pseudohypertrophy refers to muscle tissue that has been replaced by fat and connective tissue, giving it a bulky appearance with a paradoxical reduction in strength, as in Duchenne muscular dystrophy.

**Tone**

Muscle tone, which is generated by an unconscious, continuous, partial contraction of muscle, creates resistance to passive movement of a joint. Tone varies greatly based on a patient's age and state. At 28 wk of gestation, all 4 extremities are extended and there is little resistance to passive movement. Flexor tone is visible in the lower extremities at 32 wk and is palpable in the upper extremities at 36 wk; a normal-term infant's posture is characterized by flexion of all 4 extremities.

There are 3 key tests for assessing postural tone in neonates: the traction response, vertical suspension, and horizontal suspension (Fig. 590-3; see Chapters 94 and 97). To evaluate the traction response, the physician grasps the infant's hands and gently pulls the infant to a sitting position. Normally, the infant's head lags slightly behind the infant's body and then falls forward upon reaching the sitting position. To test vertical suspension, the physician holds the infant by the axillae without gripping the thorax. The infant should remain suspended with the infant's lower extremities held in flexion; a hypotonic infant will slip through the physician's hands. With horizontal suspension, the physician holds the infant prone by placing a hand under the infant's abdomen. The head should rise and the limbs should flex, but a hypotonic infant will drape over the physician's hand, forming a U shape. Assessing tone in the extremities is accomplished by observing the infant's resting position and passively manipulating the infant's limbs. When the upper extremity of a normal-term infant is pulled gently across the chest, the elbow does not quite reach the mid-sternum (scarf sign), whereas the elbow of a hypotonic infant extends beyond the midline with ease. Measurement of the popliteal angle is a useful method for documenting tone in the lower extremities. The examiner flexes the hip and extends the knee. Normal-term infants allow

![Figure 590-3 Normal tone in a full-term neonate. A, Flexed resting posture. B, Traction response. C, Vertical suspension. D, Horizontal suspension.](image-url)
Abnormalities of tone include spasticity, rigidity, and hypotonia. (Paratonia, which is rarely seen in the pediatric population, is not discussed here.) Spasticity is characterized by an initial resistance to passive movement, followed by a sudden release, referred to as the clasp-knife phenomenon. Because spasticity results from upper motor neuron dysfunction, it disproportionately affects the upper-extremity flexors and lower-extremity extensors and tends to occur in conjunction with disuse atrophy, hyperactive deep tendon reflexes, and extensor plantar reflexes (Babinski sign). In infants, spasticity of the lower extremities results in scissoring of the legs upon vertical suspension. Older children can present with prolonged commando crawling or toe-walking. Rigidity, seen with lesions of the basal ganglia, is characterized by resistance to passive movement that is equal in the flexors and extensors regardless of the velocity of movement (lead pipe). Patients with either spasticity or rigidity might exhibit opisthotonos, defined as severe hyperextension of the spine caused by hypertonia of the paraspinal muscles (Fig. 590-4), although similar posturing can be seen in patients with Sandifer syndrome (gastroesophageal reflux or hiatal hernia associated with torsional dystonia). Hypotonia refers to abnormally diminished tone and is the most common abnormality of tone in neurologically compromised neonates. A hypotonic infant is floppy and often assumes a frog-leg posture at rest. Hypotonia can reflect pathology of the cerebral hemispheres, cerebellum, spinal cord, anterior horn cell, peripheral nerve, neuromuscular junction, or muscle.

Strength
Older children are usually able to cooperate with formal strength testing, in which case muscle power is graded on a scale of 0-5 as follows: 0 = no contraction; 1 = flicker or trace of contraction; 2 = active movement with gravity eliminated; 3 = active movement against gravity; 4 = active movement against gravity and resistance; 5 = normal power. An examination of muscle power should include all muscle groups, including the neck flexors and extensors and the muscles of respiration. It is important not only to assess individual muscle groups, but also to determine the pattern of weakness (i.e., proximal vs distal; segmental vs regional). Testing for pronator drift can be helpful in localizing the lesion in a patient with weakness. This test is accomplished by having the patient extend his or her arms away from the body with the palms facing upward and the eyes closed. Together, pronation and downward drift of an arm indicate a lesion of the contralateral corticospinal tract.

Because infants and young children are not able to participate in formal strength testing, they are best assessed with functional measures. Proximal and distal strength of the upper extremities can be tested by having the child reach overhead for a toy and by watching the child manipulate small objects. In infants younger than 2 mo old, the physician can also take advantage of the palmar grasp reflex in assessing distal power and the Moro reflex in assessing proximal power. Infants with decreased strength in the lower extremities tend to have diminished spontaneous activity in their legs and are unable to support their body weight when held upright. Older children may have difficulty climbing or descending steps, jumping, or hopping. They might also use their hands to "climb up" their legs when asked to rise from a prone position, a maneuver called Gowers sign (Fig. 590-5).

Involuntary Movements
Patients with lower motor neuron or peripheral nervous system lesions might have fasciculations, which are small, involuntary muscle contractions that result from the spontaneous discharge of a single motor unit and create the illusion of a "bag of worms" under the skin. Because most infants have abundant body fat, muscle fasciculations are best observed in the tongue in this age group. Most other involuntary movements, including tics, dystonia, chorea, and athetosis, stem from disorders of the basal ganglia. Tremor seems
to be an exception, as it is thought to be mediated by cerebellothalamomotor pathways. Further detail on the individual movement disorders is provided in Chapter 597.

**Sensory Examination**
The sensory examination is difficult to perform on an infant or uncooperative child and has a relatively low yield in terms of the information it provides. A gross assessment of sensory function can be achieved by distracting the patient with an interesting toy and then touching the patient with a cotton swab in different locations. Normal infants and children indicate an awareness of the stimulus by crying, withdrawing the extremity, or pausing briefly; however, with repeated testing, they lose interest in the stimulus and begin to ignore the examiner. It is critical, therefore, that any areas of concern are tested efficiently and, if necessary, reexamined at an appropriate time.

Fortunately, isolated disorders of the sensory system are less common in the very young pediatric population than in the adult population, so detailed sensory testing is rarely warranted. Furthermore, most patients who are old enough to voice a sensory complaint are also old enough to cooperate with formal testing of light touch, pain, temperature, vibration, proprioception, and corticospensation (e.g., stereognosis, 2-point discrimination, extinction to double simultaneous stimulation). A notable exception is when the physician suspects a spinal cord lesion in an infant or young child and needs to identify a sensory level. In such situations, observation might suggest a difference in color, temperature, or perspiration, with the skin cool and dry below the level of injury.

Lightly touching the skin above the level can evoke a squirming movement or physical withdrawal. Other signs of spinal cord injury include decreased anal sphincter tone and strength and absence of the superficial abdominal, anal wink, and cremasteric reflexes.

**Reflexes**

**Deep Tendon Reflexes and the Plantar Response**
Deep tendon reflexes are readily elicited in most infants and children. In infants, it is important to position the head in the midline when assessing reflexes, because turning the head to 1 side can alter reflex tone. Reflexes are graded from 0 (absent) to +4 (markedly hyperactive), with +2 being normal. Reflexes that are 1+ or 3+ can be normal as long as they are symmetrical. Sustained clonus is always pathologic, but infants younger than 3 mo old can have 5-10 beats of clonus, and older children can have 1-2 beats of clonus, provided that it is symmetrical.

The ankle jerk is hardest to elicit, but it can usually be obtained by passively dorsiflexing the foot and then tapping on either the Achilles tendon or the ball of the foot. The knee jerk is evoked by tapping the patellar tendon. If this reflex is exaggerated, extension of the knee may be accompanied by contraction of the contralateral adductors (crossed adductor response). Hypoactive reflexes reflect lower motor neuron or cerebellar dysfunction, whereas hyperactive reflexes are consistent with upper motor neuron disease. The plantar response is obtained by stimulation of the lateral aspect of the sole of the foot, beginning at the heel and extending to the base of the toes. The Babinski sign, indicating an upper motor neuron lesion, is characterized by extension of the great toe and fanning of the remaining toes. Too vigorous stimulation may produce withdrawal, which may be misinterpreted as a Babinski sign. Plantar responses have limited diagnostic utility in neonates, because they are mediated by several competing reflexes and can be either flexor or extensor, depending on how the foot is positioned.

Asymmetry of the reflexes or plantar response is a useful lateralizing sign in infants and children.

**Primitive Reflexes**
Primitive reflexes appear and disappear at specific times during development (Table 590-2), and their absence or persistence beyond those times signifies CNS dysfunction. Although many primitive reflexes have been described, the Moro, grasp, tonic neck, and parachute reflexes are the most clinically relevant. The Moro reflex is elicited by supporting the infant in a semierect position and then allowing the infant’s head to fall backwards onto the examiner’s hand. A normal response consists of symmetric extension and abduction of the fingers and upper extremities, followed by flexion of the upper extremities and an audible cry. An asymmetric response can signify a fractured clavicle, brachial plexus injury, or hemiparesis. Absence of the Moro reflex in a term newborn is ominous, suggesting significant dysfunction of the CNS. The grasp response is elicited by placing a finger in the open palm of each hand; by 37 wk of gestation, the reflex is strong enough that the examiner can lift the infant from the bed with gentle traction. The tonic neck reflex is produced by manually rotating the infant’s head to 1 side and observing for the characteristic fencing posture (extension of the arm on the side to which the face is rotated and flexion of the contralateral arm). An obligatory tonic neck response, in which the infant becomes “stuck” in the fencing posture, is always abnormal and implies a CNS disorder. The parachute reflex, which occurs in slightly older infants, can be evoked by holding the infant's trunk and then suddenly lowering the infant as if he or she were falling. The arms will spontaneously extend to break the infant’s fall, making this reflex a prerequisite to walking.

**Coordination**
Ataxia refers to a disturbance in the smooth performance of voluntary motor acts and is usually the result of cerebellar dysfunction. Lesions to the cerebellar vermis result in unsteadiness while sitting or standing (truncal ataxia). Affected patients might have a wide-based gait or may be unable to perform tandem gait testing. Lesions of the cerebellar hemispheres cause appendicular ataxia, which may be apparent as the patient reaches for objects and performs finger-to-nose and heel-to-shin movements. Other features of cerebellar dysfunction include errors in judging distance (dysmetria), inability to inhibit a muscular action (rebound), impaired performance of rapid alternating movements (dysdiadochokinesia), intention tremor, nystagmus, scanning dysarthria, hypotonia, and decreased deep tendon reflexes. Acute ataxia suggests an infectious or postinfectious, endocrinologic, toxic, traumatic, vascular, or psychogenic process, and chronic symptoms suggest a metabolic, neoplastic, or degenerative process.

**Station and Gait**
Observation of a child’s station and gait is an important aspect of the neurologic examination. Normal children can stand with their feet close together without swaying; however, children who are unsteady may sway or even fall. On gait testing, the heels should strike either side of an imaginary line, but children with poor balance tend to walk with their legs farther apart to create a more stable base. Tandem gait
testing forces patients to have a narrow base, which highlights subtle balance difficulties.

There are a variety of abnormal gaits, many of which are associated with a specific underlying etiology. Patients with a spastic gait appear stiff-legged like a soldier. They may walk on tiptoe as a result of tightness or contractures of the Achilles tendons, and their legs may scissor as they walk. A hemiparetic gait is associated with spasticity and circumduction of the leg, as well as decreased arm swing on the affected side. Cerebellar ataxia results in a wide-based, reeling gait like a drunk person, whereas sensorineural ataxia results in a wide-based steppage gait, in which the patient lifts the legs up higher than usual in the swing phase and then slaps the foot down. A myopathic, or waddling, gait is associated with hip girdle weakness. Affected children often develop a compensatory lordosis and have other signs of proximal muscle weakness, such as difficulty climbing stairs. During gait testing, the examiner might also note hypotonia or weakness of the lower extremities; extrapyramidal movements, such as dystonia or chorea; or orthopedic deformities, such as pelvic tilt, genu recurvatum, varus or valgus deformities of the knee, pes cavus (high arches) or pes planus (flat feet), and scoliosis.

**GENERAL EXAMINATION**
Examination of other organ systems is essential because myriad systemic diseases affect the nervous system. Dystrophic features can indicate a genetic syndrome (see Chapter 108). Heart murmurs may be associated with rheumatic fever (Seydahen chorea), cardiac rhabdomyoma (tuberous sclerosis), cyanotic heart disease (cerebral abscess or thrombosis), and endocarditis (cerebral vascular occlusion). Hepatosplenomegaly can suggest an inborn error of metabolism, storage disease, HIV, or malnutrition. Cerebellar ataxia results in a wide-based, reeling gait like a drunk person, whereas xanthochromia (yellow color that results from the degradation of hemoglobin) suggests a subarachnoid hemorrhage. Xanthochromia may be absent in bloods <1 hr old, particularly when laboratories rely on visual inspection rather than spectroscopy. Xanthochromia can also occur in the setting of hyperbilirubinemia, carotenemia, and markedly elevated CSF protein. An elevated polymorphonuclear count suggests bacterial meningitis or the early phase of aseptic meningitis (see Chapter 603). CSF lymphocytosis can be seen in aseptic, tuberculous, or fungal meningitis; demyelinating diseases; brain or spinal cord tumor; immunologic disorders, including collagen vascular diseases; and chemical irritation (following myelogram, intrathecal methotrexate).

Normal CSF contains no red blood cells; thus, their presence indicates a traumatic tap or a subarachnoid hemorrhage. Progressive clearing of the blood between the first and last samples indicates a traumatic tap. Bloody CSF should be centrifuged immediately. A clear supernatant is consistent with a bloody tap, whereas xanthochromia (yellow color that results from the degradation of hemoglobin) suggests a subarachnoid hemorrhage. Xanthochromia may be absent in bloods <1 hr old, particularly when laboratories rely on visual inspection rather than spectroscopy. Xanthochromia can also occur in the setting of hyperbilirubinemia, carotenemia, and markedly elevated CSF protein. The normal CSF protein is 10-40 mg/DL in a child and as high as 120 mg/DL in a neonate. The CSF protein falls to the normal childhood range by 3 mo of age. The CSF protein may be elevated in many processes, including infectious, immunologic, vascular, and degenerative diseases, blockage of CSF flow, as well as tumors of the brain (primary CNS tumors, systemic tumors metastatic to the CNS, infiltrative acute lymphoblastic leukemia) and spinal cord. With a traumatic tap, the CSF protein is increased by approximately 1 mg/DL for every 1,000 red blood cells/mm³. Elevation of CSF immunoglobulin G, which normally represents approximately 10% of the total protein, is observed in subacute sclerosing panencephalitis, in postinfectious encephalomyelitis, and in some cases of multiple sclerosis. If the diagnosis of multiple sclerosis is suspected, the CSF should be tested for the presence of oligoclonal bands.

The CSF glucose content is approximately 60% of the blood glucose in a healthy child. To prevent a spuriously elevated blood:CSF glucose ratio in a case of suspected meningitis, it is advisable to collect the blood glucose before the lumbar puncture when the child is relatively calm. Hypoglycorrhachia is found in association with diffuse meningitis, bacterial disease, particularly bacterial and tuberculous meningitis. Wide-spread neoplastic involvement of the meninges, subarachnoid hemorrhage, disorders involving the glucose transporter protein type 1, fungal meningitis, and, occasionally, aseptic meningitis can produce low CSF glucose as well.

**SPECIAL DIAGNOSTIC PROCEDURES Lumbar Puncture and Cerebrospinal Fluid Examination**
Examination of the cerebrospinal fluid (CSF) and measurement of the pressure it creates in the subarachnoid space are essential in confirming the diagnosis of meningitis, encephalitis, and idiopathic intracranial hypertension (previously referred to as pseudotumor cerebri), and should be associated with rheumatic fever (Sydenham chorea), cardiac rhabdomyoma (tuberous sclerosis), cyanotic heart disease (cerebral abscess or thrombosis), and endocarditis (cerebral vascular occlusion). Hepatosplenomegaly can suggest an inborn error of metabolism, storage disease, HIV, or malnutrition. Cerebellar ataxia results in a wide-based, reeling gait like a drunk person, whereas xanthochromia (yellow color that results from the degradation of hemoglobin) suggests a subarachnoid hemorrhage. Xanthochromia may be absent in bloods <1 hr old, particularly when laboratories rely on visual inspection rather than spectroscopy. Xanthochromia can also occur in the setting of hyperbilirubinemia, carotenemia, and markedly elevated CSF protein. An elevated polymorphonuclear count suggests bacterial meningitis or the early phase of aseptic meningitis (see Chapter 603). CSF lymphocytosis can be seen in aseptic, tuberculous, or fungal meningitis; demyelinating diseases; brain or spinal cord tumor; immunologic disorders, including collagen vascular diseases; and chemical irritation (following myelogram, intrathecal methotrexate).

Hypoglycorrhachia is found in association with diffuse meningitis, bacterial disease, particularly bacterial and tuberculous meningitis. Wide-spread neoplastic involvement of the meninges, subarachnoid hemorrhage, disorders involving the glucose transporter protein type 1, fungal meningitis, and, occasionally, aseptic meningitis can produce low CSF glucose as well.
A Gram stain of the CSF is essential if there is a suspicion for bacterial meningitis; an acid-fast stain and India ink preparation can be used to assess for tuberculous and fungal meningitis, respectively. CSF is then plated on different culture media depending on the suspected pathogen. When indicated by the clinical presentation, it can also be helpful to assess for the presence of specific antigens (e.g., latex agglutination for Neisseria meningitidis, Haemophilus influenzae type b, or Streptococcus pneumoniae) or to obtain antibody or polymerase chain reaction studies (e.g., herpes simplex virus-1 and -2, West Nile virus, enteroviruses). INoninfectious cases, levels of CSF metabolites, such as lactate, amino acids, and enolase, can provide clues to the underlying metabolic disease.

Neuroradiologic Procedures

Skull roentgenograms have limited diagnostic utility. They can demonstrate fractures, bony defects, intracranial calcifications, or indirect evidence of increased ICP. Acutely increased ICP causes separation of the sutures, whereas chronically increased ICP is associated with erosion of the posterior clinoid processes, enlargement of the sella turcica, and increased convolutional markings.

Cranial ultrasonography is the imaging method of choice for detecting intracranial hemorrhage, periventricular leukomalacia, and hydrocephalus in infants with patent anterior fontanels. Ultrasound is less sensitive than either CT or MRI for detecting hypoxic-ischemic injury, but the use of color Doppler or power Doppler sonography, both of which show changes in regional cerebral blood flow, improve its sensitivity. In general, ultrasound is not a useful technique in older children, although it can be helpful intraoperatively when placing shunts, locating small tumors, and performing needle biopsies.

CT is a valuable diagnostic tool in the evaluation of many neurologic emergencies, as well as some nonemergent conditions. It is a noninvasive, rapid procedure that can usually be performed without sedation. CT scans use conventional x-ray techniques, meaning that they produce ionizing radiation. Because children younger than 10 yr of age are several times more sensitive to radiation than adults, it is important to consider the whether imaging is actually indicated and, if it is, whether an ultrasound or MRI might be the more appropriate study. In the emergency setting, a noncontrast CT scan can demonstrate skull fractures, pneumocephalus, intracranial hemorrhages, hydrocephalus, and impeding herniation. If the noncontrast scan reveals an abnormality and an MRI cannot be performed in a timely fashion, nonionic contrast should be used to highlight areas of breakdown in the blood-brain barrier (e.g., abscesses, tumors) and/or collections of abnormal blood vessels (e.g., arteriovenous malformations). CT is less useful for diagnosing acute infarcts in children, because radiographic changes might not be apparent for up to 24 hr. Some subtle signs of early (<24 hr) infarction include sulcal effacement, blurring of the gray-white junction, and the hyperdense middle cerebral artery sign (increased attenuation in the middle cerebral artery that is often associated with thrombosis). In the routine setting, CT imaging can be used to demonstrate intracranial calcifications or, with the addition of 3-dimensional reformating, to evaluate patients with craniofacial abnormalities or craniosynostosis. Although other pathologic processes may be visible on CT scan, MR is generally preferred because it provides a more-detailed view of the anatomy without exposure to ionizing radiation (Table 590-3).

CT angiography is a useful tool for visualizing vascular structures and is accomplished by administering a tight bolus of iodinated contrast through a large-bore intravenous catheter and then acquiring CT images as the contrast passes through the arteries.

MRI is a noninvasive procedure that is well suited for detecting a variety of abnormalities, including those of the posterior fossa and spinal cord. MR scans are highly susceptible to patient motion artifact; consequently, many children younger than age 8 yr require sedation to ensure an adequate study. (The need for sedation is beginning to change in some centers as MRI technology improves and allows for faster performance of studies.) Because the American Academy of Pediatrics recommends that infants be kept nothing by mouth (NPO) for 4 hr or longer and older children for 6 hr or longer before deep sedation, it is often difficult to obtain an MRI on an infant or young child in the acute setting. MRI can be used to evaluate for congenital or acquired brain lesions, migrational defects, dysmyelination or demyelination, posttraumatic gliosis, neoplasms, cerebral edema, and acute stroke (see Table 590-3). Paramagnetic MR contrast agents (e.g., gadolinium-diethylenetriaminepentaacetic acid [DTPA]) are efficacious in identifying areas of disruption in the blood–brain barrier, such as those occurring in primary and metastatic brain tumors, meningiitis, cerebritis, abscesses, and active demyelination. MR angiography and MR venography provide detailed images of major intracranial vascular structures and assist in the diagnosis of conditions such as stroke, vascular malformations, and cerebral venous sinus thrombosis.

MR angiography is the procedure of choice for infants and young children owing to the lack of ionizing radiation and contrast; however, CT angiography may be preferable in older children because it is faster and can eliminate the need for sedation; it is particularly useful for looking at blood vessels in the neck, where there is less interference from bone artifact than in the skull-encased brain.

Functional MRI is a noninvasive technique used to map neuronal activity during specific cognitive states and/or sensorimotor functions. Data are usually based on blood oxygenation, although they can also be based on local cerebral blood volume or flow. Functional MRI is useful for presurgical localization of critical brain functions and has several advantages over other functional imaging techniques. Specifically, functional MRI produces high-resolution images without exposure to ionizing radiation or contrast, and it allows coregistration of functional and structural images.

Proton MR spectroscopy (MRS) is a molecular imaging technique in which the unique neurochemical profile of a preselected brain region is displayed in the form of a spectrum. Many metabolites can be detected, the most common of which are N-acetylaspartate, creatine and phosphocreatine, choline, myoinositol, and lactate. Changes in the spectral pattern of a given area can yield clues to the underlying pathology, making MRS useful in the diagnosis of inborn errors of metabolism, as well as the preoperative and posttherapeutic assessment of intracranial tumors. MRS can also detect areas of cortical dysplasia in patients with epilepsy, because these patients have low N-acetylaspartate/creatine ratios. Finally, MRS may be useful in detecting hypoxic-ischemic injury in newborns in the 1st day of life, because the lactate peak enlarges and the N-acetylaspartate peak diminishes before MRI sequences become abnormal.

Catheter angiography is the gold standard for diagnosing vascular disorders of the CNS, such as arteriovenous malformations, aneurysms, arterial occlusions, and vasculitis. A 4-vessel study is accomplished by introducing a catheter into the femoral artery and then injecting contrast media into each of the internal carotid and vertebral arteries. Because catheter angiography is invasive and requires general anesthesia, it is typically reserved for treatment planning of endovascular or open procedures and for cases in which noninvasive imaging results are not diagnostic.

Positron emission tomography provides unique information on brain metabolism and perfusion by measuring blood flow, oxygen uptake, and/or glucose consumption. Positron emission tomography is an expensive technique that is gaining a following in some pediatric centers, particularly those with active epilepsy surgery programs. Single-photon emission CT using 99mTc hexamethylpropyleneamine oxime is a sensitive and inexpensive technique to study regional cerebral blood flow. Single-photon emission CT is particularly useful in assessing for vasculitis, herpes encephalitis, dysplastic cortex, and recurrent brain tumors. Positron emission tomography MRI is only available in a few pediatric centers in the United States; it provides better resolution and tissue definition than single-photon emission CT.

Electroencephalography

An electroencephalogram (EEG) provides a continuous recording of electrical activity between reference electrodes placed on the scalp. Although the genesis of the electrical activity is not certain, it likely originates from postsynaptic potentials in the dendrites of cortical neurons. Even with amplification of the electrical activity, not all potentials are recorded because there is a buffering effect of the scalp, muscles, bone, vessels, and subarachnoid fluid. EEG waves are
Normal sleep is divided into 3 stages of non–rapid eye movement sleep—designated N1, N2, and N3—and rapid eye movement sleep. N1 corresponds to drowsiness, and N3 represents deep, restorative, slow-wave sleep. Rapid eye movement sleep is rarely captured during a routine EEG but may be seen on an overnight recording. The normal waking EEG is characterized by the posterior dominant rhythm—a sinusoidal, 8-12 Hz rhythm that is most prominent over the occipital region in a state of relaxed wakefulness with the eyes closed. This rhythm first becomes apparent at 3-4 mo old, and most children have achieved the adult frequency of 8-12 Hz by age 8 yr.

from paroxysmal events that mimic epilepsy, including psychogenic nonepileptiform attacks. Long-term EEG monitoring can also be useful during medication adjustments.

**Evoked Potentials**

An evoked potential is an electrical signal recorded from the CNS following the presentation of a specific visual, auditory, or sensory stimulus. Stimulation of the visual system by a flash or patterned stimulus, such as a black-and-white checkerboard, produces visual evoked potentials (VEPs), which are recorded over the occiput and averaged in a computer. Abnormal VEPs can result from lesions to the visual pathway anywhere from the retina to the visual cortex. Many demyelinating disorders and neurodegenerative diseases, such as Tay-Sachs, Krabbe, or Pelizaeus-Merzbacher disease, or neuronal ceroid lipofuscinoses, show characteristic VEP abnormalities. Flash VEPs can also be helpful in evaluating infants who have sustained an anoxic injury; however, detection of an evoked potential does not necessarily mean that the infant will have functional vision.

**Brainstem auditory evoked responses** (BAERs) provide an objective measure of hearing and are particularly useful in neonates and in children who have failed, or are uncooperative with, audiometric testing. BAERs are abnormal in many neurodegenerative diseases of childhood and are an important tool in evaluating patients with suspected tumors of the cerebellopontine angle. BAERs can be helpful in assessing brainstem function in comatose patients, because the waveforms are unaffected by drugs or by the level of consciousness; however, they are not accurate in predicting neurologic recovery and outcome.

**Somatosensory evoked potentials** (SSEPs) are obtained by stimulating a peripheral nerve (peroneal, median) and then recording the electrical response over the cervical region and contralateral parietal somatosensory cortex. SSEPs determine the functional integrity of the dorsal column–medial lemniscal system and are useful in monitoring spinal cord function during operative procedures for scoliosis, aortic coarctation, and myelomeningocele repair. SSEPs are abnormal in many neurodegenerative disorders and are the most accurate evoked potential in the assessment of neurologic outcome following a severe CNS insult.

Bibliography
Campbell WW: DeJong’s the neurologic examination, ed 7, Philadelphia, 2012, Lippincott Williams & Wilkins.
Central nervous system (CNS) malformations are grouped into neural tube defects and associated spinal cord malformations; encephaloceles; disorders of structure specification (gray matter structures, neuronal migration disorders, disorders of connectivity, and commissure and tract formation); disorders of the posterior fossa, brainstem, and cerebellum; disorders of brain growth and size; and disorders of skull growth and shape. Classification of these conditions into syndromic, nonsyndromic, and single-gene etiologies is also important. These disorders can also be seen as isolated findings or as being a consequence of environmental exposures. Elucidation of single-gene causes has out-paced our understanding of the epigenetic and environmental mechanisms causing these malformations.

These disorders are heterogeneous in their presentation. Common presentations and clinical problems include disorders of head size and/or shape; hydrocephalus; fetal ultrasonographic brain abnormalities; neonatal encephalopathy and seizures; developmental delay, cognitive impairment, and intellectual disability; hypotonia, motor impairment, and cerebral palsy; seizures, epilepsy, and drug-resistant epilepsy; cranial nerve dysfunction; and spinal cord dysfunction.

## 591.1 Neural Tube Defects

Stephen L. Kinsman and Michael V. Johnston

Neural tube defects (NTDs) account for the largest proportion of congenital anomalies of the CNS and result from failure of the neural tube to close spontaneously between the 3rd and 4th wk of in utero development. Although the precise cause of NTDs remains unknown, evidence suggests that many factors, including hyperthermia, drugs (valproic acid), malnutrition, low red cell folate levels, chemicals, maternal obesity or diabetes, and genetic determinants (mutations in folate-responsive or folate-dependent enzyme pathways) can adversely affect normal development of the CNS from the time of conception. In some cases, an abnormal maternal nutritional state or exposure to radiation before conception increases the likelihood of a congenital CNS malformation. The major NTDs include spina bifida occulta, meningocele, myelomeningocele, encephalocele, anencephaly, caudal regression syndrome, dermal sinus, tethered cord, syringomyelia, diastematomyelia, and lipoma involving the conus medullaris and/or filum terminale and the rare condition iniencephaly.

The human nervous system originates from the primitive ectoderm that also develops into the epidermis. The ectoderm, endoderm, and mesoderm form the three primary germ layers that are developed by the 3rd wk. The endoderm, particularly the notochordal plate and the intraembryonic mesoderm, induces the overlying ectoderm to develop the neural plate in the 3rd wk of development (Fig. 591-1A). Failure of normal induction is responsible for most of the NTDs, as well as disorders of prosencephalic development. Rapid growth of cells within the neural plate causes further invagination of the neural groove and differentiation of a conglomerate of cells, the neural crest, which migrate laterally on the surface of the neural tube (Fig. 591-1B). The notochordal plate becomes the centrally placed notochord, which acts as a foundation around which the vertebral column ultimately develops. With formation of the vertebral column, the notochord undergoes involution and becomes the nucleus pulposus of the intervertebral disks. The neural crest cells differentiate to form the peripheral nervous system, including the spinal and autonomic ganglia and the ganglia of cranial nerves V, VII, VIII, IX, and X. In addition, the neural crest forms the leptomeninges, as well as Schwann cells, which are responsible for myelination of the peripheral nervous system. The dura is thought to arise from the paraxial mesoderm. In the region of the embryo destined to become the head, similar patterns exist. In this region, the notochord is replaced by the prechordal mesoderm.

In the 3rd wk of embryonic development, invagination of the neural groove is completed and the neural tube is formed by separation from the overlying surface ectoderm (see Fig. 591-1C). Initial closure of the neural tube is accomplished in the area corresponding to the future junction of the spinal cord and medulla and moves rapidly both caudally and rostrally. For a brief period, the neural tube is open at both ends, and the neural canal communicates freely with the amniotic cavity (see Fig. 591-1D). Failure of closure of the neural tube allows excretion of fetal substances (α-fetoprotein [AFP], acetylcholinesterase) into the amniotic fluid, serving as biochemical markers for a NTD. Prenatal screening of maternal serum for AFP in the 16th-18th wk of gestation is an effective method for identifying pregnancies at risk for fetuses with NTDs in utero. Normally, the rostral end of the neural
Bibliography
tube closes on the 23rd day and the caudal neuropore closes by a process of secondary neurulation by the 27th day of development, before the time that many women realize they are pregnant.

The embryonic neural tube consists of 3 zones: ventricular, mantle, and marginal (see Fig. 591-1F). The ependymal layer consists of pluripotential, pseudostratified, columnar neuroepithelial cells. Specific neuroepithelial cells differentiate into primitive neurons or neuroblasts that form the mantle layer. The marginal zone is formed from cells in the outer layer of the neuroepithelium, which ultimately becomes the white matter. Glioblasts, which act as the primitive supportive cells of the CNS, also arise from the neuroepithelial cells in the ependymal zone. They migrate to the mantle and marginal zones and become future astrocytes and oligodendrocytes. The importance of other pathways of progenitor cell generation and migration are also being elucidated. It is likely that microglia originate from mesenchymal cells at a later stage of fetal development when blood vessels begin to penetrate the developing nervous system.

591.2 Spina Bifida Occulta
(Occult Spinal Dysraphism)

Stephen L. Kinsman and Michael V. Johnston

Spina bifida occulta is a common anomaly consisting of a midline defect of the vertebral bodies without protrusion of the spinal cord or meninges. Most patients are asymptomatic and lack neurologic signs, and the condition is usually of no consequence. Some consider the term spina bifida occulta to denote merely a posterior vertebral body fusion defect. This simple defect does not have an associated spinal cord malformation. Other clinically more significant forms of this closed spinal cord malformation are more correctly termed occult spinal dysraphism. In most of these cases, there are cutaneous manifestations such as a hemangioma, discoloration of the skin, pit, lump, dermal sinus, or hairy patch (Fig. 591-2).

A dermoid sinus usually forms a small skin opening, which leads into a narrow duct, sometimes indicated by protruding hairs, a hairy patch, or a vascular nevus. Dermoid sinuses occur in the midline at the sites where meningoceles or encephaloceles can occur: the lumbosacral region or occiput, respectively and occasionally in the cervical or thoracic area. Dermoid sinus tracts can pass through the dura, acting as a conduit for the spread of infection. Recurrent meningitis of occult origin should prompt careful examination for a small sinus tract in the posterior midline region, including the back of the head. Lower back sinuses are usually above the gluteal fold and are directed cephalad. Tethered spinal cord syndrome may also be an associated problem. Diastematomyelia commonly has bony abnormalities of the spinal cord, including syringomyelia, diastematomyelia, lipoma, fatty flum, dermal sinus, and/or a tethered cord. A spine x-ray in these cases might show bone defects or may be normal. All cases of occult spinal dysraphism are best investigated with MRI (Fig. 591-3). Initial screening in the neonate may include ultrasonography, but MRI is more accurate at any age.

A dermoid sinus usually forms a small skin opening, which leads into a narrow duct, sometimes indicated by protruding hairs, a hairy patch, or a vascular nevus. Dermoid sinuses occur in the midline at the sites where meningoceles or encephaloceles can occur: the lumbosacral region or occiput, respectively and occasionally in the cervical or thoracic area. Dermoid sinus tracts can pass through the dura, acting as a conduit for the spread of infection. Recurrent meningitis of occult origin should prompt careful examination for a small sinus tract in the posterior midline region, including the back of the head. Lower back sinuses are usually above the gluteal fold and are directed cephalad. Tethered spinal cord syndrome may also be an associated problem. Diastematomyelia commonly has bony abnormalities that require surgical intervention along with untethering of the spinal cord.

An approach to imaging of the spine in patients with cutaneous lesions is noted in Table 591-1.

591.3 Meningocele

Stephen L. Kinsman and Michael V. Johnston

A meningocele is formed when the meninges herniate through a defect in the posterior vertebral arches or the anterior sacrum. The spinal cord is usually normal and assumes a normal position in the spinal canal, although there may be tethering of the cord, syringomyelia, or diastematomyelia. A fluctuant midline mass that might transilluminate occurs along the vertebral column, usually in the lower back. Most meningoceles are well covered with skin and pose no immediate threat to the patient. Careful neurologic examination is mandatory. Orthopedic and urologic examination should also be considered. In asymptomatic children with normal neurologic findings and full-thickness skin covering the meningocele, surgery may be delayed or sometimes not performed.

Before surgical correction of the defect, the patient must be thoroughly examined with the use of plain x-rays, ultrasonography, and MRI to determine the extent of neural tissue involvement, if any, and associated anomalies, including diastematomyelia, lipoma, and possible clinically significant tethered spinal cord. Urologic evaluation usually includes cystometrygram to identify children with neurogenic bladder who are at risk for renal deterioration. Patients with leaking cerebrospinal fluid (CSF) or a thin skin covering should undergo immediate surgical treatment to prevent meningitis. A CT scan or MRI of the head is recommended for children with a meningocele because of the association with hydrocephalus in some cases. An anterior meningocele projects into the pelvis through a defect in the sacrum. Symptoms of constipation and bladder dysfunction develop due to the increasing size of the lesion. Female patients might have associated anomalies of the genital tract, including a rectovaginal fistula and vaginal septa. Plain x-rays demonstrate a defect in the sacrum, and CT scanning or MRI outlines the extent of the meningocele and any associated anomalies.

591.4 Myelomeningocele

Stephen L. Kinsman and Michael V. Johnston

Myelomeningocele represents the most severe form of dysraphism, a so-called aperta or open form, involving the vertebral column and spinal cord, which occurs with an incidence of approximately 1 in 4,000 live births.

ETIOLOGY

The cause of myelomeningocele is unknown, but as with all neural tube closure defects, including anencephaly, a genetic predisposition exists; the risk of recurrence after 1 affected child is 3-4% and increases to 10% with 2 prior affected children. Both epidemiologic evidence and the presence of substantial familial aggregation of anencephaly, myelomeningocele, and craniorachischis indicate heredity, on a polygenic basis, as a significant contributor to the etiology of NTDs. Nutritional and environmental factors have a role in the etiology of myelomeningocele as well.

Folate is intricately involved in the prevention and etiology of NTDs. Folate functions in single-carbon transfer reactions and exists in many chemical forms. Folic acid (pteroylmonoglutamic acid), which is the most oxidized and stable form of folate, occurs rarely in food but is the form used in vitamin supplements and in fortified food products, particularly flour. Most naturally occurring folates (food folate) are pteroylpolyglutamates, which contain 1-6 additional glutamate molecules joined in a peptide linkage to the γ-carboxyl of glutamate. Folate coenzymes are involved in DNA synthesis, purine synthesis, generation of formate into the formate pool, and amino acid interconversion; the conversion of homocysteine to methionine provides methionine for the synthesis of S-adenosylmethionine (SAMe, an agent important for in vivo methylation). Mutations in the genes encoding the enzymes involved in homocysteine metabolism may play a role in the pathogenesis of myelomeningocele. These enzymes include 5,10-methylenetetrahydrofolate reductase, cystathionine β-synthase, and methionine synthase. An association between a thermolabile variant of 5,10-methylenetetrahydrofolate reductase and mothers of children with NTDs might account for up to 15% of preventable NTDs. Maternal periconceptional use of folic acid supplementation reduces the incidence of NTDs in pregnancies at risk by at least 50%. To be effective, folic acid supplementation should be initiated before conception and continued until at least the 12th wk of gestation, when neurulation is complete. The mechanisms by which folic acid prevents NTDs remain poorly understood.

PREVENTION

The U.S. Public Health Service has recommended that all women of childbearing age and who are capable of becoming pregnant take 0.4 mg of folic acid daily. If, however, a pregnancy is planned in high-risk women (previously affected child), supplementation should be started with 4 mg of folic acid daily, beginning 1 mo before the time of the planned conception. The modern diet provides about half the daily requirement of folic acid. To increase folic acid intake, fortification of flour, pasta, rice, and cornmeal with 0.15 mg folic acid per 100 g was mandated in the United States and Canada in 1998. The added folic acid is insufficient to maximize the prevention of preventable NTDs. Therefore, informative educational programs and folic acid vitamin supplementation remain essential for women planning a pregnancy and possibly for all women of childbearing age. In addition, women should also strive to consume food folate from a varied diet. Certain drugs, including drugs that antagonize folic acid, such as trimethoprim and the anticonvulsants carbamazepine, phenytoin, phenobarbital, and primidone, increase the risk of myelomeningocele. The anticonvulsant valproic acid causes NTDs in approximately 1-2% of pregnancies when administered during pregnancy. Some epilepsy clinicians recommend that all female patients of childbearing potential who take anticonvulsant medications also receive folic acid supplements. There may be a threshold for ideal red blood cell folate levels (900-1,000 nmol/L), which is associated with a markedly reduced risk of NTDs.

CLINICAL MANIFESTATIONS

Myelomeningocele produces dysfunction of many organs and structures, including the skeleton, skin, and gastrointestinal and genitourinary tracts, in addition to the peripheral nervous system and the CNS. A myelomeningocele may be located anywhere along the neuraxis, but the lumbosacral region accounts for at least 75% of the cases. The extent and degree of the neurologic deficit depend on the location of the myelomeningocele and the associated lesions. A lesion in the low sacral region causes bowel and bladder incontinence associated with anesthesia in the perineal area but with no impairment of motor function. Newborns with a defect in the midlumbar or high lumbosacral region typically have either a sac-like cystic structure covered by a thin layer of partially epithelialized tissue (Fig. 591-4) or an exposed flat
neural placode without overlying tissues. When a cyst or membrane is present, remnants of neural tissue are visible beneath the membrane, which occasionally ruptures and leaks CSF.

Examination of the infant shows a flaccid paralysis of the lower extremities, an absence of deep tendon reflexes, a lack of response to touch and pain, and a high incidence of lower-extremity deformities (clubfeet, ankle and/or knee contractures, and subluxation of the hips). Some children have constant urinary dribbling and a relaxed anal sphincter. Other children do not leak urine and in fact have a high-pressure bladder and sphincter dyssynergy. Thus, a myelomeningocele above the midlumbar region tends to produce lower motor neuron signs because of abnormalities and disruption of the conus medullaris and above spinal cord structures.

Infants with myelomeningocele typically have increased neurologic deficit as the myelomeningocele extends higher into the thoracic region. These infants sometimes have an associated kyphotic gibbus that requires neonatal orthopedic correction. Patients with a myelomeningocele in the upper thoracic or cervical region usually have a very minimal neurologic deficit and, in most cases, do not have hydrocephalus. They can have neurogenic bladder and bowel.

Hydrocephalus in association with a type II Chiari malformation develops in at least 80% of patients with myelomeningocele. Generally, patients with sacral myelomeningocele have a very low risk of hydrocephalus. The possibility of hydrocephalus developing after the neonatal period should always be considered, no matter what the spinal level. Ventricular enlargement may be indolent and slow growing or may be rapid causing a bulging anterior fontanel, dilated scalp veins, setting-sun appearance of the eyes, irritability, and vomiting in association with an increased head circumference. Approximately 15% of infants with hydrocephalus and Chiari II malformation develop symptoms of hindbrain (brainstem) dysfunction, including difficulty feeding, choking, stridor, apnea, vocal cord paralysis, pooling of secretions, and spasticity of the upper extremities, which, if untreated, can lead to death. This Chiari crisis is caused by downward herniation of the medulla and cerebellar tonsils through the foramen magnum, as well as endogenous malformations in the cerebellum and brainstem, causing dysfunction.

TREATMENT

Management and supervision of a child and family with a myelomeningocele require a multidisciplinary team approach, including surgeons, other physicians, and therapists, with 1 individual (often a pediatrician) acting as the advocate and coordinator of the treatment program. The news that a newborn child has a devastating condition such as myelomeningocele causes parents to feel considerable grief and anger. They need time to learn about the condition and its associated complications and to reflect on the various procedures and treatment plans. A knowledgeable individual in an unhurried and nonterrorizing setting must give the parents the facts, along with general prognostic information and management strategies and timelines. If possible, discussions with other parents of children with NTDs are helpful in resolving important questions and issues.

Surgery is often done within a day or so of birth but can be delayed for several days (except when there is a CSF leak) to allow the parents time to begin to adjust to the shock and to prepare for the multiple procedures and inevitable problems that lie ahead. Evaluation of other congenital anomalies and renal function can also be initiated before surgery. Most pediatric centers aggressively treat the majority of infants with myelomeningocele. After repair of a myelomeningocele, most infants require a shunting procedure for hydrocephalus. If symptoms or signs of hindbrain dysfunction appear, early surgical decompression of the posterior fossa is indicated. Clubfeet can require taping or casting, and dislocated hips may require operative procedures.

Careful evaluation and reassessment of the genitourinary system are some of the most important components of the management. Teaching the parents, and, ultimately, the patient, to regularly catheterize a neurogenic bladder is a crucial step in maintaining a low residual volume and bladder pressure that prevents urinary tract infections and reflux leading to pyelonephritis, hydronephrosis, and bladder damage. Latex-free catheters and gloves must be used to prevent development of latex allergy. Periodic urologic cultures and assessment of renal function, including serum electrolytes and creatinine as well as renal scans, vesicourethrogram, renal ultrasonography, and cystometrograms, are obtained according to the risk status and progress of the patient and the results of the physical examination. This approach to urinary tract management has greatly reduced the need for urologic diversionary procedures and significantly decreased the morbidity and mortality associated with progressive renal disease in these patients. Some children can become continent with surgical implantation of an artificial urinary sphincter (these are used less often) or bladder augmentation at a later age.

Although incontinence of fecal matter is common and is socially unacceptable during the school years, it does not pose the same organ-damaging risks as urinary dysfunction, but occasionally fecal impaction and/or meconium develop. Many children can be bowel-trained with a regimen of timed enemas or suppositories that allows evacuation at a predetermined time once or twice a day. Special attention to low anorectal tone and enema administration and retention is often required. Appendicostomy for antegrade enemas may also be helpful (see Chapter 23.4).

Functional ambulation is the wish of each child and parent and may be possible, depending on the level of the lesion and on intact function of the ilioptos muscles. Almost every child with a sacral or lumbosacral lesion obtains functional ambulation; approximately half the children with higher defects ambulate with the use of braces, other orthotic devices, and canes. Ambulation is often more difficult as adolescence approaches and body mass increases. Deterioration of ambulatory function, particularly during earlier years, should prompt referral for evaluation of tethered spinal cord and other neurosurgical issues.

In utero surgical closure of a spinal lesion has been successful in a few centers. Preliminary reports suggest a lower incidence of hindbrain abnormalities and hydrocephalus (fewer shunts) as well as improved motor outcomes. This suggests that the defects may be progressive in utero and that prenatal closure might prevent the development of further loss of function. In utero diagnosis is facilitated by maternal serum AFP screening and by fetal ultrasonography (see Chapter 96).

PROGNOSIS

For a child who is born with a myelomeningocele and who is treated aggressively, the mortality rate is 10-15%, and most deaths occur before age 4 yr, although life-threatening complications occur at all ages. At least 70% of survivors have normal intelligence, but learning problems and seizure disorders are more common than in the general population. Previous episodes of meningitis or ventriculitis adversely affect intellectual and cognitive function. Because myelomeningocele is a chronic disabling condition, periodic and consistent multidisciplinary follow-up is required for life. Renal dysfunction is one of the most important determinants of mortality.

591.5 Encephalocele

Stephen L. Kinsman and Michael V. Johnston

Two major forms of dysraphism affect the skull, resulting in protrusion of tissue through a bony midline defect, called cranium bifidum. A cranial meningocele consists of a CSF-filled meningeal sac only, and a cranial encephalocele contains the sac plus cerebral cortex, cerebellum, or portions of the brainstem. Microscopic examination of the neural tissue within an encephalocele often reveals abnormalities. The cranial defect occurs most commonly in the occipital region at or
Bibliography

Anencephaly

An anencephalic infant presents a distinctive appearance with a large defect of the calvarium, meninges, and scalp associated with a rudimentary brain, which results from failure of closure of the rostral neuropore, the opening of the anterior neural tube. The primitive brain consists of portions of connective tissue, vessels, and neuropia. The cerebral hemispheres and cerebellum are usually absent, and only a residuum of the brainstem can be identified. The pituitary gland is hypoplastic, and the spinal cord pyramidal tracts are missing owing to the absence of the cerebral cortex. Additional anomalies include folding of the ears, cleft palate, and congenital heart defects in 10-20% of cases. Most anencephalic infants die within several days of birth.

The incidence of anencephaly approximates 1 in 1,000 live births; the greatest incidence is in Ireland, Wales, and Northern China. The recurrence risk is approximately 4% and increases to 10% if a couple has had 2 previously affected pregnancies. Many factors, in addition to genetics, are implicated as a cause of anencephaly, including low socioeconomic status, nutritional and vitamin deficiencies, and a large number of environmental and toxic factors. It is very likely that several noxious stimuli interact on a genetically susceptible host to produce anencephaly. The incidence of anencephaly has been decreasing since the 1990s. Approximately 50% of cases of anencephaly have associated polyhydramnios. Couples who have had an anencephalic infant should have successive pregnancies monitored, including amniocentesis, determination of AFP levels, and ultrasound examination between the 14th and 16th wk of gestation. Prenatal folic acid supplementation decreases the risk of this condition.

 Disorders of Neuronal Migration

Disorders of neuronal migration can result in minor abnormalities with little or no clinical consequence (small heterotopia of neurons) or devastating abnormalities of CNS structure and/or function (intellectual disability, seizures, lissencephaly, and schizencephaly, particularly the open-lip form) (Fig. 591-5). One of the most important mechanisms in the control of neuronal migration is the radial glial fiber system that guides neurons to their proper site. Migrating neurons attach to the radial glial fiber and then disembark at predetermined sites to form, ultimately, the precisely designed 6-layered cerebral cortex. Another important mechanism is the tangential migration of progenitor neurons destined to become cortical interneurons. The severity and the extent of the disorder are related to numerous factors, including the timing of a particular insult and a host of environmental and genetic contributors. Some cortical malformations may be from somatic mutations, as exemplified by kinesin gene mutations in patients with pachygyria.

LISSENCEPHALY

Lissencephaly, or agyria, is a rare disorder that is characterized by the absence of cerebral convolutions and a poorly formed sylvian fissure, giving the appearance of a 3-4 mm fetal brain. The condition is probably a result of faulty neuroblast migration during early embryonic life and is usually associated with enlarged lateral ventricles and heterotopias in the white matter. In some forms, there is a 4-layered cortex, rather than the usual 6-layered one, with a thin rim of periventricular white matter and numerous gray heterotopias visible by microscopic examination. Milder forms of lissencephaly also exist.

Figure 591-5 T1-weighted MRI scan demonstrating band heterotopia. A thin layer of white matter (black arrow) lies between the band of heterotopic gray matter and the cortical surface. Failure of cortical organization with lissencephaly is present in both frontal lobes (white arrow).
**Bibliography**

Several genes have been identified that are a cause of these conditions.

**POLYMICROGYRIAS**

Polymicrogyria is characterized by an augmentation of small convolutions separated by shallow enlarged sulci. Epilepsy, including drug-resistant forms, is a common feature. Truncation of the KBP gene has been implicated in a family with multiple members with polymicrogyria.

**SCHIZENCEPHALY**

Schizencephaly is the presence of unilateral or bilateral clefts within the cerebral hemispheres owing to an abnormality of morphogenesis (Fig. 591-7). The cleft may be fused or unfused and, if unilateral and large, may be confused with a porencephalic cyst. Not infrequently, the borders of the cleft are surrounded by abnormal brain, particularly microgyria. MRI is the study of choice for elucidating schizencephaly and associated malformations.

When the clefts are bilateral, many patients are severely intellectually challenged, with seizures that are difficult to control, and microcephalic, with spastic quadriplegia. Some cases of bilateral schizencephaly are associated with septooptic dysplasia and endocrinologic disorders. Unilateral schizencephaly is a common cause of congenital hemiparesis. It remains controversial whether genetic causes of schizencephaly exist. Some gene mutations are seen in cases of familial schizencephaly.

**NEURONAL HETEROTOPIAS**

Subtypes of neuronal heterotopias include periventricular nodular heterotopias, subcortical heterotopia (including band-type), and marginal glioneuronal heterotopias. Intractable seizures are a common feature.
FOCAL CORTICAL DYSPLASIAS
Focal cortical dysplasias consist of abnormal cortical lamination in a discrete area of cortex. High-resolution, thin-section MRI can reveal these areas sometimes in the setting of drug-resistant epilepsy.

PORENCHEPHALY
Porencephaly is the presence of cysts or cavities within the brain that result from developmental defects or acquired lesions, including infarction of tissue. True porencephalic cysts are most commonly located in the region of the sylvian fissure and typically communicate with the subarachnoid space, the ventricular system, or both. They represent developmental abnormalities of cell migration and are often associated with other malformations of the brain, including microcephaly, abnormal patterns of adjacent gyri, and encephalocele. Affected infants tend to have many problems, including intellectual disability, spastic hemiparesis or quadriplegia, optic atrophy, and seizures.

Several risk factors for porencephalic cyst formation have been identified, including hemorrhagic venous infarctions; various thrombophilias such as protein C deficiency and factor V Leiden mutations; perinatal alloimmune thrombocytopenia; von Willebrand disease; maternal warfarin use; maternal cocaine use; congenital infections; perinatal alloimmune thrombocytopenia; von Willebrand disease; maternal cocaine use; congenital infections; maternal warfarin use; maternal cocaine use; congenital infections; and maternal abdominal trauma. Mutations in the COL4A1 gene have been described in cases of familial porencephaly.

Pseudoporencephalic cysts characteristically develop during the perinatal or postnatal period and result from abnormalities (infarction, hemorrhage) of arterial or venous circulation. These cysts tend to be unilateral, do not communicate with a fluid-filled cavity, and are not associated with abnormalities of cell migration or CNS malformations. Infants with pseudoporencephalic cysts present with hemiparesis and focal seizures in the 1st yr of life and sometimes present with neonatal encephalopathy or as a floppy newborn or infant.

Bibliography is available at Expert Consult.

591.8 Agenesis of the Corpus Callosum
Stephen L. Kinsman and Michael V. Johnston

Agenesis of the corpus callosum consists of a heterogeneous group of disorders that vary in expression from severe intellectual and neurologic abnormalities to the asymptomatic and normally intelligent patient (Fig. 591-8). The corpus callosum develops from the commissural plate that lies in proximity to the anterior neuropore. Either a direct insult to the commissural plate or disruption of the genetic signaling that specifies and organizes this area during early embryogenesis causes agenesis of the corpus callosum.

It is often said that the outcome of agenesis of the corpus callosum is dictated by the company it keeps. When agenesis of the corpus callosum is an isolated phenomenon, the patient may be normal. When it is accompanied by brain anomalies from cell migration defects, such as heterotopias, polymicrogyria, and pachygyria (broad, wide gyri), patients often have significant neurologic abnormalities, including intellectual disability, microcephaly, hemiparesis, diplegia, and seizures.

The anatomic features of agenesis of the corpus callosum are best depicted on MRI or CT scan and include widely separated frontal horns with an abnormally high position of the third ventricle between the lateral ventricles. MRI precisely outlines the extent of the corpus callosum defect.

Absence of the corpus callosum may be inherited as an X-linked recessive trait or as an autosomal dominant trait and on occasion as an autosomal recessive trait. The condition may be associated with specific chromosomal disorders, particularly trisomy 8 and trisomy 18. Single-gene mutations have also been identified, usually in association with other anomalies. Agenesis of the corpus callosum is also seen in some metabolic disorders (Table 591-2).

Aicardi syndrome represents a complex disorder that affects many systems and is typically associated with agenesis of the corpus callosum, distinctive choriorretinal lacunae, and infantile spasms. Patients are almost all female, suggesting a genetic abnormality of the X chromosome (it may be lethal in males during fetal life). Seizures become evident during the 1st few mo and are typically resistant to anticonvulsants. An electroencephalogram shows independent activity recorded from both hemispheres as a result of the absent corpus callosum and shows often hemihyypsarrhythmia. All patients have severe intellectual disability and can have abnormal vertebrae that may be fused or only partially developed (hemivertebrae). Abnormalities of the retina, including circumscribed pits or lacunae and coloboma of the optic disc, are the most characteristic findings of Aicardi syndrome.

Colpocephaly refers to an abnormal enlargement of the occipital horns of the ventricular system and can be identified as early as the fetal period. It is often associated with agenesis of the corpus callosum, but it can occur in isolation. It is also associated with microcephaly. It can also be seen in anatomic megalencephaly, such as is associated with Sotos syndrome.

HOLOPROSENCEPHALY
Holoprosencephaly is a developmental disorder of the brain that results from defective formation of the prosencephalon and
Bibliography
inadequate induction of forebrain structures. The abnormality, which represents a spectrum of severity, is classified into 3 groups: alobar, semilobar, and lobar, depending on the degree of the cleavage abnormality (Fig. 591-9). A fourth type, the middle interhemispheric fusion variant or syntelencephaly, involves a segmental area of noncleavage, actually a nonseparation, of the posterior frontal and parietal lobes. Facial abnormalities, including cyclopia, synophthalmia, cebocephaly, single nostril, choanal atresia, solitary central incisor tooth, and premaxillary agenesis are common in severe cases, because the prechordal mesoderm that induces the ventral prosencephalon is also responsible for induction of the median facial structures. Milder facial abnormalities are seen in milder forms. Alobar holoprosencephaly is characterized by a single ventricle, an absent falx, and nonseparated deep cerebral nuclei. Care must be taken not to overdiagnose holoprosencephaly based on ventricular abnormalities alone. Evidence of nonseparated midline deep-brain structures, such as caudate, putamen, globus pallidus, and hypothalamus, is the critical element for diagnosis.

Affected children with the alobar type have high mortality rates, but some live for years. Mortality and morbidity with milder types are more variable, and morbidity is less severe. Care must be taken not to prognosticate severe outcomes in all cases. The incidence of holoprosencephaly ranges from 1 in 5,000-16,000 live births. A prenatal diagnosis can be confirmed by ultrasonography after the 10th wk of gestation for more severe types, but fetal MRI at later gestational ages gives far greater anatomic, and therefore diagnostic, precision.

The cause of holoprosencephaly is often not identified. There appears to be an association with maternal diabetes. Chromosomal abnormalities, including deletions of chromosomes 7q and 3p, 21q, 2p, 18p, and 13q, as well as trisomy 13 and 18, account for upwards of 50% of all cases. Other gene symbols are omitted from this section.

‡Many of these also may consistently have a thin of dysplastic corpus callosum, such as Sotos’ syndrome or agenesis of the corpus callosum (ACC) with spastic paraparesis (SPG11). The overlap between ACC and these conditions is still under investigation. Other gene symbols are omitted from this section.

Bibliography

innervation by the oculomotor nerve of the lateral rectus muscle. Abnormalities of cranial nerve development have been demonstrated in this condition.

Less common than Duane retraction syndrome and Möbius syndrome are the group of disorders known as congenital fibrosis of the extraocular muscles. Congenital fibrosis of the extraocular muscles is characterized by severe restriction of eye movements and ptosis from abnormal oculomotor and trochlear nerve development and/or from abnormalities of extraocular muscle innervation.

**BRAINSTEM AND CEREBELLAR DISORDERS**

Disorders of the posterior fossa structures include abnormalities of not only the brainstem and cerebellum, but also the CSF spaces. Commonly encountered malformations include Chiari malformation, Dandy-Walker malformation, arachnoid cysts, mega cisterna magna, persisting Blake pouch, Joubert syndrome, rhombencephalosynapsis, Lhermitte-Duclos disease, and the pontocerebellar hypoplasias.

**Chiari malformation** is the most common malformation of the posterior fossa and hindbrain. It consists of herniation of the cerebellar tonsils though the foramen magnum. Often, there is also an associated developmental abnormality of the bones of the skull base leading to a small posterior fossa. Cases can be either asymptomatic or symptomatic. When symptoms develop, they often do not do so until late childhood. Symptoms include headaches that are worse with straining and other maneuvers that increase intracranial pressure. Symptoms of brainstem compression such as dysphoria, oropharyngeal dysfunction, spasticity, tinnitus, and vertigo can occur. Obstructive hydrocephalus and/or syringomyelia can also occur.

**Dandy-Walker malformation** is part of a continuum of posterior fossa anomalies that include cystic dilation of the fourth ventricle, hypoplasia of the cerebellar vermis, hydrocephalus, and an enlarged posterior fossa with elevation of the lateral venous sinuses and the tentorium. Extracranial anomalies are also seen. Variable degrees of neurologic impairment are usually present. The etiology of Dandy-Walker malformation includes chromosomal abnormalities, single gene disorders, and exposure to teratogens.

**Arachnoid cysts** of the posterior fossa can be associated with hydrocephalus. Mega cisterna magna is characterized by an enlarged CSF space inferior and dorsal to the cerebellar vermis and when present in isolation may be considered a normal variant. Persisting Blake pouch is a cyst that obstructs the subarachnoid space and is associated with hydrocephalus.

**Joubert syndrome** is an autosomal recessive disorder (ciliopathy) with significant genetic heterogeneity that is associated with cerebellar vermis hypoplasia and the pontomesencephalic molar tooth sign (a deepening of the interpeduncular fossa with thick and straight superior cerebellar peduncles) (Fig. 591-10). It is associated with hypotonia, ataxia (as toddler), characteristic breathing abnormalities including episodic apnea and hyperpnea (which improves with age), global developmental delay, nystagmus, strabismus, ptosis, and oculomotor apraxia. There can be many associated systemic features (Joubert syndrome and related disorders) including progressive retinal dysplasia (Leber congenital amaurosis), coloboma, congenital heart disease, microcystic kidney disease, liver fibrosis, polydactyly, tongue protrusion, and soft tissue tumors of the tongue (Fig. 591-11).

**Rhombencephalosynapsis** is an absent or small vermis associated with a nonseparation or fusion of the deep midline cerebellar structures. Ventricleomegaly or hydrocephalus is often seen. There is variable clinical presentation from normal to cognitive and language impairments, epilepsy, and spasticity. **Lhermitte-Duclos disease** is a dysplastic gangliocytoma of the cerebellum leading to focal enlargement of the cerebellum and macrocephaly, cerebellar signs, and seizures.

**Pontocerebellar hypoplasias** are a group of disorders characterized by impairment of cerebellar and pontine development together with histopathologic features of neuronal death and glial replacement. Clinical features tend to be nonspecific and include hypotonia, feeding difficulties, developmental delay, and breathing difficulties. Classification, associations, and causes include type I (with features of anterior

**Classification of disorders of cranial nerve, brainstem, and cerebellum development remains anatomic, but future classification systems will likely be based on the molecular biology of brain development based on the genes involved and the roles they play in orchestrating brain architecture.**

**CONGENITAL CRANIAL DYSINNERRVATION DISORDERS**

Absence of the cranial nerves or the corresponding central nuclei has been described in several conditions and includes the optic nerve defects, congenital ptosis, Marcus Gunn phenomenon (sucking jaw movements causing simultaneous eyelid blinking; this congenital synkinesis results from abnormal innervation of the trigeminal and oculomotor nerves), trigeminal and auditory nerves defects, and cranial nerves IX, X, XI, and XII defects. Increased understanding of these disorders and their genetic causes has led to the term **congenital cranial dysinnervation disorders**.

Optic nerve hypoplasia can occur in isolation or as part of the septo-optic dysplasia complex (de Morsier syndrome). Septo-optic dysplasia can be caused by a mutation in the *HESXI* gene.

**Möbius syndrome** is characterized by bilateral facial weakness, which is often associated with paralysis of the abducens nerve. Hypoplasia or agenesis of brainstem nuclei, as well as absent or decreased numbers of muscle fibers, has been reported. Affected infants present in the newborn period with facial weakness, causing feeding difficulties owing to a poor suck. The immobile, dull facies might give the incorrect impression of intellectual impairment; the prognosis for normal development is excellent in most cases. The facial appearance of Möbius syndrome has been improved by facial surgery.

**Duane retraction syndrome** is characterized by congenital limitation of horizontal globe movement and some globe retraction on attempted adduction and is believed to be the result of abnormal
Figure 591-10 Neuroimaging findings in a 2-yr-old child with pure Joubert syndrome (upper panels) compared to a healthy control (lower panels). A, Parasagittal T1-weighted image shows the thickened, elongated, and horizontally orientated superior cerebellar peduncles (white arrow). B, Midsagittal T1-weighted image demonstrates a moderate hypoplasia and dysplasia of the cerebellar vermis (white arrows) with secondary distortion and enlargement of the fourth ventricle with rostral shifting of the fastigium (white arrowhead). A deepened interpeduncular fossa is also noted. C, Axial T1-weighted image at the level of the pontomesencephalic junction shows the molar tooth sign with a deepened interpeduncular fossa (white arrowhead) and elongated, thickened, and horizontally orientated superior cerebellar peduncles (white arrows). Additionally, the cerebellar vermis appears to be hypoplastic and its remnants dysplastic. D, Coronal T1-weighted image reveals the thickened superior cerebellar peduncles (white arrows). (From Romani M, Micalizzi A, Valente EM: Joubert syndrome: congenital cerebellar ataxia with the molar tooth. Lancet Neurol 12:894–905, 2013, Fig. 1.)

Figure 591-11 Spectrum of organ involvement in Joubert syndrome and classification in clinical subgroups (in bold). Chorioretinal colobomas are more frequently found in the subgroup of Joubert syndrome with liver involvement but can be present also in other subgroups. Similarly, polydactyly (especially if preaxial or mesoaxial) is invariably present in the Orofaciiodigital type VI subgroup, but postaxial polydactyly is frequently observed also in association with other Joubert syndrome phenotypes. Other clinical features outside the circles occur more rarely, without a specific association to a clinical subgroup. CNS, central nervous system; COR, cerebello oculorenal; K, kidney involvement; L, liver involvement; MTS, molar tooth sign; OFDVI, orofaciiodigital type VI syndrome. (From Romani M, Micalizzi A, Valente EM: Joubert syndrome: congenital cerebellar ataxia with the molar tooth. Lancet Neurol 12:894–905, 2013, Fig. 3.)
Congenital Microcephaly

Causes of Microcephaly

Significant fever during 1st 4-6 wk has been reported to cause microcephaly, seizures, and facial anomalies. Although there are many causes of microcephaly, abnormalities in neuronal migration during fetal development, including heterotopias of neuronal cells and cytoarchitectural derangements, are often found. Microcephaly may be subdivided into 2 main groups: primary (genetic) microcephaly and secondary (nongenetic) microcephaly. A precise diagnosis is important for genetic counseling and for prediction for future pregnancies.

ETIOLOGY

Primary microcephaly refers to a group of conditions that usually have no associated malformations and follow a mendelian pattern of inheritance or are associated with a specific genetic syndrome. Affected infants are usually identified at birth because of a small head circumference. The more common types include familial and autosomal dominant microcephaly and a series of chromosomal syndromes that are summarized in Table 591-3. Primary microcephaly is also associated with at least 7 gene loci, and 7 single etiologic genes have been identified. It is known as autosomal recessive primary microcephaly and has autosomal inheritance. Many X-linked causes of microcephaly are caused by gene mutations that lead to severe structural brain anomalies.

591.10 Microcephaly

Stephen L. Kinsman and Michael V. Johnston

Microcephaly is defined as a head circumference that measures more than 3 SD below the mean for age and sex. This condition is relatively common, particularly among developmentally delayed children.

Bibliography
malformations such as lissencephaly, holoprosencephaly, polymicrogyria, cobbledstone dysplasia, neuronal heterotopia, pontocerebellar hypoplasia; these should be sought on MRI. Secondary microcephaly results from a large number of noxious agents that can affect a fetus in utero or an infant during periods of rapid brain growth, particularly the 1st 2 yr of life.

Acquired microcephaly can be seen in conditions such as Rett, Seckel, and Angelman syndromes and in encephalopathy syndromes associated with severe seizure disorders.

**CLINICAL MANIFESTATIONS AND DIAGNOSIS**

A thorough family history should be taken, seeking additional cases of microcephaly or disorders affecting the nervous system. It is important to measure a patient’s head circumference at birth to diagnose microcephaly as early as possible. A very small head circumference implies a process that began early in embryonic or fetal development. An insult to the brain that occurs later in life, particularly beyond the age of 2 yr, is less likely to produce severe microcephaly. Serial head circumference measurements are more meaningful than a single determination, particularly when the abnormality is minimal. The head circumference of each parent and sibling should be recorded.

Laboratory investigation of a microcephalic child is determined by the history and physical examination. If the cause of the microcephaly is unknown, the mother’s serum phenylalanine level should be determined. High phenylalanine serum levels in an asymptomatic mother can produce marked brain damage in an otherwise normal nonprenatal infant. A karyotype and/or array comparative genomic hybridization study is obtained if a chromosomal syndrome is suspected or if the child has abnormal facies, short stature, and additional congenital anomalies. MRI is useful in identifying structural abnormalities of the brain such as lissencephaly, pachgyria, and polymicrogyria, and CT scanning is useful to detect intracerebral calcification. Additional studies include a fasting plasma and urine amino acid analysis; serum ammonia determination; toxoplasmosis, rubella, cytomegalovirus, and herpes simplex (TORCH) titers as well as HIV testing of the mother and child; and a urine sample for the culture of cytomegalovirus. Single-gene mutations as a cause of both primary microcephaly and syndromic microcephaly are being increasingly identified.

**TREATMENT**

Once the cause of microcephaly has been established, the physician must provide accurate and supportive genetic and family counseling. Because many children with microcephaly are also intellectually challenged, the physician must assist with placement in an appropriate program that will provide for maximal development of the child (see Chapter 36).

**591.11 Hydrocephalus**

Stephen L. Kinsman and Michael V. Johnston

Hydrocephalus is not a specific disease; it represents a diverse group of conditions that result from impaired circulation and/or absorption of CSF or, in rare circumstances, from increased production of CSF by a choroid plexus papilloma (Table 591-4). Because megalencephaly is often discovered as part of an evaluation for hydrocephalus in children with macrocephaly, it is included in this section.

**PHYSIOLOGY**

The CSF is formed primarily in the ventricular system by the choroid plexus, which is situated in the lateral, third, and fourth ventricles. Although most CSF is produced in the lateral ventricles, approximately 25% originates from extrachoroidal sources, including the capillary endothelium within the brain parenchyma. There is active neurogenic control of CSF formation because adrenergic and cholinergic nerves innervate the choroid plexus. Stimulation of the adrenergic system diminishes CSF production, whereas excitation of the cholinergic nerves may double the normal CSF production rate. In a normal child, approximately 20 mL/hr of CSF is produced. The total volume of CSF approximates 50 mL in an infant and 150 mL in an adult. Most of the CSF is extraventricular. The choroid plexus forms CSF in several stages; through a series of intricate steps, a plasma ultrafiltrate is ultimately processed into a secretion, the CSF.

CSF flow results from the pressure gradient that exists between the ventricular system and venous channels. Intraventricular pressure may be as high as 180 mm H2O in the normal state, whereas the pressure in the superior sagittal sinus is in the range of 90 mm H2O. Normally, CSF flows from the lateral ventricles through the foramina of Monro into the 3rd ventricle. It then traverses the narrow aqueduct of Sylvius, which is approximately 3 mm long and 2 mm in diameter in a child, to enter the fourth ventricle. The CSF exits the fourth ventricle through the paired lateral foramina of Luschka and the midline foramen of Magendie into the cisterns at the base of the brain. Hydrocephalus resulting from obstruction within the ventricular system is called obstructive or noncommunicating hydrocephalus. The CSF then circulates from the basal cisterns posteriorly through the cistern system and over the convexities of the cerebral hemispheres. CSF is absorbed primarily by the arachnoid villi through tight junctions of their endothelium by the pressure forces that were noted earlier. CSF is absorbed to a much lesser extent by the lymphatic channels directed to the paranasal sinuses, along nerve root sleeves, and by the choroid plexus itself. Hydrocephalus resulting from obliteration of the subarachnoid cisterns or malfunction of the arachnoid villi is called nonobstructive or communicating hydrocephalus.

**PATHOPHYSIOLOGY AND ETIOLOGY**

Obstructive or noncommunicating hydrocephalus develops most commonly in children because of an abnormality of the aqueduct of Sylvius or a lesion in the fourth ventricle. Aqueductal stenosis results from an abnormally narrow aqueduct of Sylvius that is often associated with

branching or forking. In a small percentage of cases, aqueductal stenosis is inherited as a sex-linked recessive trait. These patients occasionally have minor neural tube closure defects, including spina bifida occulta. Rarely, aqueductal stenosis is associated with neurofibromatosis. Aqueductal gliosis can also give rise to hydrocephalus. As a result of neonatal meningitis or a subarachnoid hemorrhage in a premature infant, the ependymal lining of the aqueduct is interrupted and a brisk glial response results in complete obstruction. Intrauterine viral infections can also produce aqueductal stenosis followed by hydrocephalus, and parainsufficiency of the fourth ventricle in the posterior fossa and midline cerebellar hypoplasia, which results from a developmental failure of the roof of the fourth ventricle during embryogenesis (Fig. 591-14). Approximately 90% of patients have hydrocephalus, and a significant number of children have associated anomalies, including agenesis of the posterior cerebellar vermis and corpus callosum. Infants present with a rapid increase in head size and a prominent occiput. Transillumination of the skull may be positive. Most children have evidence of long-tract signs, cerebellar ataxia, and delayed motor and cognitive milestones, probably due to the associated structural anomalies. The Dandy-Walker malformation is managed by shunting the cystic cavity (and on occasion the ventricles as well) in the presence of hydrocephalus.

**CLINICAL MANIFESTATIONS**

The clinical presentation of hydrocephalus is variable and depends on many factors, including the age at onset, the nature of the lesion causing obstruction, and the duration and rate of increase of the intracranial pressure (ICP). In an infant, an accelerated rate of enlargement of the head is the most prominent sign. In addition, the anterior fontanel is wide open and bulging, and the scalp veins are dilated. The forehead is broad, and the eyes might deviate downward because of impingement of the dilated suprapineal recess on the brainstem tectum, producing the setting-sun eye sign. Long-tract signs, including brisk tendon reflexes, spasticity, clonus (particularly in the lower extremities), and Babinski sign, are common owing to stretching and disruption of the corticospinal fibers originating from the leg region of the motor cortex. In an older child, the cranial sutures are less accommodating so that the signs of hydrocephalus may be subtler. Irritability, lethargy, poor appetite, and vomiting are common to both age groups, and headache is a prominent symptom in older patients. A gradual change in personality and deterioration in academic productivity suggest a slowly progressive form of hydrocephalus. With regard to other clinical signs, serial measurements of the head circumference often indicate an increased velocity of growth. Percussion of the skull might produce a cracked pot sound or MacEwen sign, indicating separation of the sutures. A foreshortened occiput suggests Chiari malformation, and a prominent occiput suggests the Dandy-Walker malformation. Papilledema, abducens nerve palsies, and pyramidal tract signs, which are most evident in the lower extremities, are apparent in many cases.

**Chiari malformation** consists of 2 major subgroups. Type I typically produces symptoms during adolescence or adult life and is usually not associated with hydrocephalus. Patients complain of recurrent headache, neck pain, urinary frequency, and progressive lower-extremity spasticity. The deformity consists of displacement of the cerebellar tonsils into the cervical canal (Fig. 591-12). Syrinx of the spinal cord, especially the cervical region should be looked for on MRI imaging. Although the pathogenesis is unknown, a prevailing theory suggests that obstruction of the caudal portion of the fourth ventricle during embryogenesis, and results in elongation of the fourth ventricle and kinking of the brainstem, with displacement of the inferior vermis, pons, and medulla into the cervical canal and the Dandy-Walker syndrome.

Nonobstructive or communicating hydrocephalus most commonly follows a subarachnoid hemorrhage, which is usually a result of intraventricular hemorrhage in a premature infant. Blood in the subarachnoid spaces can cause obliteration of the cisterns or arachnoid villi and obstruction of CSF flow. Pneumococcal and tuberculous meningitis have a propensity to produce a thick, tenacious exudate that obstructs the basal cisterns, and intrauterine infections can also destroy the CSF pathways. Leukemic infiltrates can seed the subarachnoid space and produce communicating hydrocephalus.

**Figure 591-12** Sagittal MR scan of a patient with Chiari malformation type I. Cerebellar tonsils are displaced through the foramen magnum (white bar) to the lower aspect of C2 with clear crowding at the foramen. A syrinx (white asterisk) is visible extending from C3 to T2. (From Yassari R, Frim D: Evaluation and management of the Chiari malformation type 1 for the primary care pediatrician, Pediatr Clin North Am 51:477–490, 2004.)

Approximately 10% of type II malformations produce symptoms during infancy, consisting of stridor, weak cry, and apnea, which may be relieved by shunting or by decompression of the posterior fossa. A more indolent form consists of abnormalities of gait, spasticity, and increasing incoordination (including the arms and hands) during childhood.

Plain skull radiographs show a small posterior fossa and a widened cervical canal. CT scanning with contrast and MRI display the cerebellar tonsils protruding downward into the cervical canal and the hindbrain abnormalities. The anomaly is treated by surgical decompression, but asymptomatic or mildly symptomatic patients may be managed conservatively.

The Dandy-Walker malformation consists of a cystic expansion of the fourth ventricle in the posterior fossa and midline cerebellar hypoplasia, which results from a developmental failure of the roof of the fourth ventricle during embryogenesis (Fig. 591-14). Approximately 90% of patients have hydrocephalus, and a significant number of children have associated anomalies, including agenesis of the posterior cerebellar vermis and corpus callosum. Infants present with a rapid increase in head size and a prominent occiput. Transillumination of the skull may be positive. Most children have evidence of long-tract signs, cerebellar ataxia, and delayed motor and cognitive milestones, probably due to the associated structural anomalies. The Dandy-Walker malformation is managed by shunting the cystic cavity (and on occasion the ventricles as well) in the presence of hydrocephalus.

**DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS**

Investigation of a child with hydrocephalus begins with the history. Familial cases suggest X-linked or autosomal hydrocephalus secondary to aqueductal stenosis. A past history of prematurity with intracranial
Examination includes careful inspection, palpation, and auscultation of the skull and spine. The occipitofrontal head circumference is recorded and compared with previous measurements. The size and configuration of the anterior fontanel are noted, and the back is inspected for abnormal midline skin lesions, including tufts of hair, lipoma, or angioma that might suggest spinal dysraphism. The presence of a prominent forehead or abnormalities in the shape of the occiput can suggest the pathogenesis of the hydrocephalus. A cranial bruit is audible in association with many cases of vein of Galen arteriovenous malformation. Transillumination of the skull is positive with massive dilation of the ventricular system or in the Dandy-Walker syndrome. Inspection of the eyegrounds is mandatory because the finding of chorioretinitis suggests an intrauterine infection, such as toxoplasmosis, as a cause of the hydrocephalus. Papilledema is observed in older children but is rarely present in infants because the cranial sutures separate as a result of the increased pressure.

Plain skull films typically show separation of the sutures, erosion of the posterior clinoids in an older child, and an increase in convolutional markings (beaten-silver appearance) on the inside of the skull with long-standing increased ICP. The CT scan and/or MRI along with ultrasonography in an infant are the most important studies to identify the specific cause and severity of hydrocephalus.

The head might appear enlarged (and can be confused with hydrocephalus) secondary to a thickened cranium resulting from chronic anemia, rickets, osteogenesis imperfecta, and epiphysial dysplasia. Chronic subdural collections can produce bilateral parietal bone prominence. MRI has revealed the common occurrence of benign external hydrocephalus, a growth-limited condition where intervention is rarely required. Various metabolic and degenerative disorders of the CNS produce megalencephaly as a result of abnormal storage of substances within the brain parenchyma. These disorders include lysosomal diseases (Tay-Sachs disease, gangliosidosis, and the mucopolysaccharidoses), the aminoacidurias (maple syrup urine disease), and the leukodystrophies (metachromatic leukodystrophy, Alexander disease, Canavan disease). In addition, cerebral gigantism (Sotos syndrome), other overgrowth syndromes and neurofibromatosis are characterized by increased brain mass. Familial megalencephaly is inherited as an autosomal dominant trait and is characterized by delayed motor milestones and hypotonia but normal or near-normal intelligence. Measurement of parents’ head circumferences is necessary to establish the diagnosis.

**Figure 591-13** A midsagittal T1-weighted MRI of a patient with type II Chiari malformation. The cerebellar tonsils (white arrow) have descended below the foramen magnum (black arrow). Note the small, slitlike fourth ventricle, which has been pulled into a vertical position.

**Figure 591-14** Dandy-Walker cyst. A, Axial CT scan (preoperative) showing large posterior fossa cyst (Dandy-Walker cyst; large arrows) and dilated lateral ventricles (small arrows), a complication secondary to cerebrospinal fluid (CSF) pathway obstruction at the fourth ventricular outlet. B, Same patient, with a lower axial CT scan showing splaying of the cerebellar hemispheres by the dilated fourth ventricle (Dandy-Walker cyst). The dilated ventricles proximal to the fourth ventricle again show CSF obstruction caused by the Dandy-Walker cyst. C, MRI of the same patient showing decreased size of the Dandy-Walker cyst and temporal horns (arrows) after shunting. The incomplete vermis (small arrow) now becomes recognizable.
MEGALENCEPHALY
Megalencephaly is an anatomic disorder of brain growth defined as a brain weight:volume ratio >98th percentile for age (or ≥2 SD above the mean) that is usually accompanied by macrocephaly (an occipitofrontal circumference >98th percentile). Various stages and degenerative diseases are associated with megalencephaly, but anatomic and genetic causes exist as well. The most common cause of anatomic megalencephaly is benign familial megalencephaly. This condition is easily diagnosed by careful family history and measurement of the parents’ head circumferences (occipitofrontal circumferences). On the other hand, macrocephaly is a known feature of more than 100 syndromes.

Anatomic megalencephaly is usually apparent at birth, and head growth continues to run parallel to the upper percentiles. Sometimes, in some syndromes, increased occipitofrontal circumference is the presenting sign. Neuroimaging is critical in identifying the various structural and gyral abnormalities seen in syndromic macrocephaly and determining whether anatomic megalencephaly exists.

Common megalencephaly-associated macrocephaly syndromes include syndromes with prenatal and/or postnatal somatic overgrowth such as Sotos, Simpson-Golabi-Behmel, fragile X, Weaver, macrocephaly-cutis marmorata telangiectatica congenita, and Bannayan-Ruvalcaba-Riley syndromes, and syndromes without somatic overgrowth such as FG, Greig cephalopolysyndactyly, acrocallosal, and Gorlin.

Sotos syndrome (cerebral gigantism) is the most common megalencephalic syndrome, with 50% of patients having prenatal macrocephaly and 100% of patients having macrocephaly by age 1 yr. Early postnatal overgrowth normalizes by adulthood. Facial features include high forehead, prominent mandible, and malar flushing. Hypotonia, poor coordination, and speech delay are common. Most children show cognitive impairment, ranging from mild to severe.

HYDRANENCEPHALY
Hydranencephaly may be confused with hydrocephalus. The cerebral hemispheres are absent or represented by membranous sacks with remnants of frontal, temporal, or occipital cortex dispersed over the membrane. The midbrain and brainstem are relatively intact (Fig. 591-15).

The cause of hydranencephaly is unknown, but bilateral occlusion of the internal carotid arteries during early fetal development would explain most of the pathologic abnormalities. Affected infants can have a normal or enlarged head circumference at birth that grows at an excessive rate postnatally. Transillumination shows an absence of the cerebral hemispheres. The child is irritable, feeds poorly, develops seizures and spastic quadriaparesis, and has little or no cognitive development.

A ventriculoperitoneal shunt prevents massive enlargement of the cranium.

TREATMENT
Therapy for hydrocephalus depends on the cause. Medical management, including the use of acetazolamide and furosemide, can provide temporary relief by reducing the rate of CSF production, but long-term results have been disappointing. Most cases of hydrocephalus require extracranial shunts, particularly a ventriculoperitoneal shunt. Endoscopic third ventriculostomy has evolved as a viable approach and criteria have been developed for its use, but the procedure might need to be repeated to be effective. Ventricular shunting may be avoided with this approach. The major complications of shunting are occlusion (characterized by headache, papilledema, emesis, mental status changes) and bacterial infection (fever, headache, meningismus), usually caused by Staphylococcus epidermidis. With meticulous preparation, the shunt infection rate can be reduced to <5%. The results of intrauterine surgical management of fetal hydrocephalus have been poor (possibly because of the high rate of associated cerebral malformations in addition to the hydrocephalus) except for some promise in cases of hydrocephalus associated with fetal meningomyelocele.

PROGNOSIS
Prognosis depends on the cause of the dilated ventricles and not on the size of the cortical mantle at the time of operative intervention, except in cases in which the cortical mantle has been severely compressed and stretched. Hydrocephalic children are at increased risk for various developmental disabilities. The mean intelligence quotient is reduced compared with the general population, particularly for performance tasks as compared with verbal abilities. Many children have abnormalities in memory function. Vision problems are common, including strabismus, visuospatial abnormalities, visual field defects, and optic atrophy with decreased acuity secondary to increased ICP. The visual evoked potential latencies are delayed and take some time to recover after correction of the hydrocephalus. Although most hydrocephalic children are pleasant and mild mannered, some children show aggressive and delinquent behavior. Accelerated pubertal development in patients with shunted hydrocephalus or myelomeningocele is relatively common, possibly because of increased gonadotropin secretion in response to increased ICP. It is imperative that hydrocephalic children receive long-term follow-up in a multidisciplinary setting.

Bibliography
DEVELOPMENT AND ETIOLOGY

The bones of the cranium are well developed by the 5th mo of gestation (frontal, parietal, temporal, and occipital) and are separated by sutures and fontanels. The brain grows rapidly in the 1st several yr of life and is normally not impeded because of equivalent growth along the suture lines. The cause of craniosynostosis is unknown, but the prevailing hypothesis suggests that abnormal development of the base of the skull creates exaggerated forces on the dura that act to disrupt normal cranial suture development. Genetic factors have been identified for some isolated and for many syndromic causes of craniosynostosis (Table 591-5).

CLINICAL MANIFESTATIONS AND TREATMENT

Most cases of craniosynostosis are evident at birth and are characterized by a skull deformity that is a direct result of premature suture fusion. Palpation of the suture reveals a prominent bony ridge, and fusion of the suture may be confirmed by plain skull roentgenograms, CT scan, or bone scan in ambiguous cases (Table 591-6).

Premature closure of the sagittal suture produces a long and narrow skull, or scaphocephaly, the most common form of craniosynostosis. Scaphocephaly is associated with a prominent occiput, a broad forehead, and a small or absent anterior fontanel. The condition is sporadic, is more common in males, and often causes difficulties during labor because of cephalopelvic disproportion. Scaphocephaly does not produce increased ICP or hydrocephalus, and results of neurologic examination of affected patients are normal.

Frontal plagiocephaly is the next most common form of craniosynostosis and is characterized by unilateral flattening of the forehead, elevation of the ipsilateral orbit and eyebrow, and a prominent ear on the corresponding side. The condition is more common in females and is the result of premature fusion of a coronal and sphenofrontal suture. Surgical intervention produces a cosmetically pleasing result. When imaging does not reveal a closed suture, positional factors are of primary importance.

Occipital plagiocephaly is most often a result of positioning during infancy and is more common in an immobile child or a child with a disability, but fusion or sclerosis of the lambdoid suture can cause unilateral occipital flattening and bulging of the ipsilateral frontal bone. Trigonocephaly is a rare form of craniosynostosis caused by premature fusion of the metopic suture. These children have a keel-shaped forehead and hypotelorism and are at risk for associated developmental abnormalities of the forebrain. Milder forms of metopic ridging are more common. Turricephaly refers to a cone-shaped head from premature fusion of the coronal, and often sphenofrontal and frontoethmoidal, sutures. The kleeblattschädel deformity is a peculiarly shaped skull that resembles a cloverleaf. Affected children have very prominent temporal bones, and the remainder of the cranium is constricted. Hydrocephalus is a common complication.

Premature fusion of only 1 suture rarely causes a neurologic deficit. In this situation, the sole indication for surgery is to enhance the child’s cosmetic appearance, and the prognosis depends on the suture involved.

and on the degree of disfigurement. Neurologic complications, including hydrocephalus and increased ICP, are more likely to occur when 2 or more sutures are prematurely fused, in which case operative intervention is essential. The role of early repositioning efforts and therapy for torticollis and the use of cranial molding devices are beyond the scope of this review.

The most prevalent genetic disorders associated with craniosynostosis include Crouzon, Apert, Carpenter, Chotzen, and Pfeiffer syndromes. Crouzon syndrome is characterized by premature craniosynostosis and is inherited as an autosomal dominant trait. The shape of the head depends on the timing and order of suture fusion but most often is a compressed back-to-front diameter or brachycephaly resulting from bilateral closure of the coronal sutures. The orbits are underdeveloped, and ocular proptosis is prominent. Hypoplasia of the maxilla and orbital hypertelorism are typical facial features.

Apert syndrome has many features in common with Crouzon syndrome. Apert syndrome is usually a sporadic condition, although autosomal dominant inheritance can occur. It is associated with premature fusion of multiple sutures, including the coronal, sagittal, squamosal, and lambdoid sutures. The facies tend to be asymmetric, and the eyes are less proptotic than in Crouzon syndrome. Apert syndrome is characterized by syndactyly of the 2nd, 3rd, and 4th fingers, which may be joined to the thumb and the 5th finger. Similar abnormalities often occur in the feet. All patients have progressive calcification and fusion of the bones of the hands, feet, and cervical spine.

Carpenter syndrome is inherited as an autosomal recessive condition, and the many fusions of sutures tend to produce the kleeblattschädel skull deformity. Soft tissue syndactyly of the hands and feet is always present, and intellectual disability is common. Additional but less common abnormalities include congenital heart disease, corneal opacities, coxa valga, and genu valgum.

Chotzen syndrome is characterized by asymmetric craniosynostosis and plagiocephaly. The condition is the most prevalent of the genetic syndromes and is inherited as an autosomal dominant trait. It is associated with facial asymmetry, ptosis of the eyelids, shortened fingers, and soft tissue syndactyly of the 2nd and 3rd fingers.

Pfeiffer syndrome is most often associated with turricephaly. The eyes are prominent and widely spaced, and the thumbs and great toes are short and broad. Partial soft-tissue syndactyly may be evident. Most cases appear to be sporadic, but autosomal dominant inheritance has been reported.

Mutations of the fibroblast growth factor receptor (FGFR) gene family have been shown to be associated with phenotypically specific types of craniosynostosis. Mutations of the FGFR1 gene located on chromosome 8 result in Pfeiffer syndrome; a similar mutation of the FGFR2 gene causes Apert syndrome. Identical mutations of the FGFR2 gene can result in both Pfeiffer and Crouzon phenotypes.

Each of the genetic syndromes poses a risk of additional anomalies, including hydrocephalus, increased ICP, papilledema, optic atrophy resulting from abnormalities of the optic foramina, respiratory problems secondary to a deviated nasal septum or choanal atresia, and disorders of speech and deafness. Cranietectomy is mandatory for management of increased ICP, and a multidisciplinary craniofacial team is essential for the long-term follow-up of affected children. Craniosynostosis may be surgically corrected with good outcomes and relatively low morbidity and mortality, especially for nonsyndromic infants.

Bibliography is available at Expert Consult.
Bibliography

Deformational plagiocephaly (DP), also known as positional plagiocephaly, is the development of cranial flattening and asymmetry in the infant as a result of extrinsic molding forces placed on the skull, such as consistently sleeping on the same area of the head. Since the suggestion to place sleeping infants on their backs to sleep for the prevention of the sudden infant death syndrome, the incidence of DP has risen dramatically, and this has caused concern for parents and clinicians in the primary care setting.

**EPIDEMIOLOGY AND ETIOLOGY**

**Incidence**

The incidence is frequent at 6 wk of age (16%), greatest at 4 mo of age (up to 20%), and then decreases over the next 3 yr (7% at 12 mo and 3.3% at 24 mo). It generally resolves completely by 2-3 yr of age. The American Academy of Pediatrics started a campaign in the 1990s that resulted in the recommendation to place infants on their backs or sides while sleeping, which resulted in a 40% decrease in sudden infant death syndrome cases. Within 4 yr, craniofacial centers and primary care offices reported a 600% increase in referrals for plagiocephaly, which was previously reported to be approximately 1 in 300 infants. This may be a result of increasing awareness or early referral, as point prevalence has not changed in the past 40 yr.

Infants cannot reposition their heads in the 1st few wk of life and are not able to hold their own heads up until about 4 mo of age. It is for this reason that DP is most severe around 4 mo of age. It is also during this time that an infant’s head circumference is rapidly increasing: about 2 cm/month in the 1st 3 mo, 1 cm/month from 4-6 mo of age, and 0.5 cm/month after 6 mo of age. Around 6 mo of age, an infant has developed head control, and this ability to actively reposition their own head allows for the gradual improvement of the cranial shape because of pressure offloading and continued brain growth.

**Risk Factors**

Congenital torticollis, positional preference when sleeping, and lower levels of activity are especially prominent in patients with DP. Table 592-1 delineates other risk factors. Many of these risk factors cannot be prevented, but sleeping supine with the head always turned to the same side has been found to predict DP independent of the other factors, and this can be prevented. There may be an association between developmental delay and DP. Although not causal, studies have found significant differences in gross motor development such as sitting up, crawling, and rolling back to side, between babies with and without DP.

Causes

Prenatal causes of DP include uterine compression and intracranial constraint, such as occurs with oligohydramnios or multifetus gestation. Postnatal causes of DP include infant sleeping position and congenital muscular torticollis.

Muscular torticollis is a condition that is present in as many as 1 in 6 newborns and causes continuous tightening of muscles in the neck preventing passive rotation. It is thought that this condition typically precedes the development of cranial deformity. However, head position preference may result from cervical asymmetry that leads to torticollis and later flattening of a side of the skull from acquired positional preference (see Chapter 680.1).

Sleeping position plays a major role in the incidence of DP. When an infant continuously sleeps with the same part of the skull resting on a flat surface, a continuous force is placed in this area. During this time of rapid skull development, the growth is inhibited at the area where it rests on a hard surface, causing a “flat spot.” Because of this inhibition, growth is increased in opposite directions causing a deformation that can be distinguished from other types of plagiocephaly.

EXAMINATION AND DIFFERENTIATING BETWEEN DEFORMATIONAL PLAGIOCEPHALY AND CRANIOSYNOSTOSIS

Abnormal head shape in an infant is distressing for parents. DP is a clinical diagnosis. Management also requires accurate counseling about its cause and treatment. It is especially important to be able to rule out craniosynostosis as a primary cause for cranial asymmetry in infants, as management of this condition is very different from that of DP and requires immediate referral to a craniofacial surgeon for evaluation (see Chapter 591.12). Craniosynostosis occurs in approximately 1 in 2,000 live births and results in plagiocephaly as a consequence of the early closure of skull sutures. Craniosynostosis must be distinguished from DP because the management is different. Lamboiodal craniosynostosis, although extremely rare (1 in 300,000 live births), presents with features most similar to those of DP. It can be distinguished from DP by a variety of historical and physical findings. Bila
eral coronal synostosis also presents very similarly to posterior DP.

History and Physical Exam

Tables 592-2 and 592-3 outline the key components of history and physical examination.

Observation of the cranial shape as well as ear displacement are the first steps. It is critical to observe the child anteriorly, laterally, and from a vertex view. When cranial shape is viewed from above, DP typically looks like a parallelogram, and the ear on the same side of the flat or bald spot is displaced anteriorly. In lamboiodal craniosynostosis, the head has a trapezoid shape and the ear on the same side as the flat spot is posteriorly displaced (Fig. 592-1).

Palpation will help to differentiate these 2 conditions. Craniosynostosis presents with palpable ridges along the suture, whereas DP does not. Additionally, patients with craniosynostosis will not have mobile calvarial bones. This can be tested by applying gentle pressure on 2

adjacent skull bones separated by a suspected synostotic suture. If the plates do not move relative to each other, then the suspicion for craniosynostosis is raised.

Verifying neck muscle tone and range of motion is a key part of the exam because it helps in evaluating motor development and in diagnosing congenital torticollis. Resistance to passive motion raises the concern for torticollis. Decreased tone should prompt further evaluation of motor development. Infants do not gain the muscle control to turn or lift their heads until approximately 4 mo of age, and delays in motor development could increase the infant’s risk of DP at later ages than those at which it usually occurs. Decreased range of motion can also be seen in cervical spine abnormalities, although this is rare. Early recognition of these conditions is critical in treatment, management, and outcome.

Accurate and consistent measurements will help to distinguish etiologies and manage infants presenting with an abnormal-shape skull. Along with the usual head circumference measurements, the clinician should also measure cranial width, length, and transcranial diameter (as shown in Figure 592-2), which is best performed with calipers. These measurements allow the clinician to diagnose, determine severity, and monitor the plagiocephaly.

- Cranial vault asymmetry: Ratio of oblique measurements. This is difficult to implement because different physicians and authors propose varying points to use for these measurements
- One technology for the evaluation of the severity and improvement over time of DP is the 3-dimensional photographic system. Advantages of this system include an easy and comfortable ability to image in an unbiased manner. Similarly, the use of laser scanners for the prefabrication scans for helmets is frequently employed by orthotists.
- After observations and measurements the clinician can determine the type and severity of the DP (Table 592-4 and Fig. 592-3). For lateral DP, bossing of the occiput occurs opposite the flattened deformity and the ear on the same side as the flat area can be anteriorly displaced. This type of DP is typically associated with infants who have torticollis or a head position preference to 1 side. Transdiagonal diameter is typically abnormal in this type of plagiocephaly, and this measurement is the gold standard for determining severity.
- In posterior DP, the occiput is uniformly flattened, temporal bossing can occur, and the ears are normal. It is usually associated with large head size and a history of limited activity or mobility. Cephalic index is increased with posterior DP.
- Time and accurate exam records can help in management. If deformation is worsening when DP typically begins to demonstrate improving head shape, craniosynostosis should be suspected.

**TREATMENT**

**Prevention**

Sleep position should be monitored and varied. Alternating the infant’s head to face the head and foot of the crib on alternate nights will allow the infant to sleep facing into the room without always lying on the same side of the head. Consistently alternating sleeping position early on allows the infant to have equal time on both sides of the occiput, and this will become a pattern the infant is used to. Infants who have

**Figure 592-3** Types of deformational plagiocephaly. (From Looman WS, Flannery AB: Evidence-based care of the child with deformational plagiocephaly, part I: assessment and diagnosis. J Pediatr Health Care 26:242–250, 2012, Fig. 1.)
an obvious positional preference to a particular side will take more
time and effort in purposefully repositioning them counter to their
preference. Parents must be counseled in the benefit of this strategy
in preventing bald spots or flat spots that can progress to cranial
deformity.

“Tummy time” is the term used to describe the infant’s awake time
spent lying on their stomach. The suggested amount of tummy time is
10-15 minutes at least 3 times a day. Reassure parents that sleep is
the only time during which the prone position should be avoided, and
educate the parents as to the benefits for the infant of awake prone
positioning to help progression of motor development.

**Treatment Options**
Cranial asymmetry from DP does not usually spontaneously improve,
nor do the more-severe manifestations of facial and ear asymmetry
disappear. Once a flat spot develops, it is unlikely that the infant will
be able to overcome the pull to lie on the same spot in time to allow
for reversal of the asymmetry.

“Watch-and-wait” management is not recommended in infants
with DP. Evidence suggests that, at a minimum, repositioning and
physiotherapy should be initiated as soon as asymmetry is observed.

Repositioning and physiotherapy (RPPT) include the counseling
and teaching for parents as to positional changes and tummy time in
their child as well as referral to physical therapy in the case of
congenital torticollis. RPPT is the optimal treatment choice for patients
younger than 4 mo of age who have mild or moderately severe DP. The
earliest types of behavioral modifications can be as simple as increasing
tummy time, or repositioning the infant’s crib such that everything
interesting in the room is on the side opposite the DP.

Molding therapy (helmet therapy) is the use of an orthotic helmet
to promote the resolution of cranial asymmetry while the infant’s head
is still rapidly growing. Orthotic helmets do not actively mold the skull;
rather, they protect the areas that are flat and allow the child to “grow
into” the flat spot. Studies have shown helmet therapy to achieve cor-
rection 3 times faster and better than repositioning alone. This therapy
is still debated because of its expense, time requirements, coverage and
side effects (irritation, rashes, and pressure sores). The most recent
studies suggest that combined treatment with helmet therapy and
RPPT is the most beneficial management of infants older than 4 mo
with severe DP or with worsening of mild/moderate DP trialed on
RPPT. Infants with severe DP should be considered for helmet therapy
at any age.

Studies suggest helmet therapy should be started for significant DP
between 4 and 8 mo and continued for 7-8 mo. Parents should be
counseled on the commitment involved in this treatment as helmets
need to be worn more than 20 hr a day.

Patients with craniosynostosis require surgery. Sometimes, a
molding helmet can be used as an adjunctive therapy after surgery but
never as monotherapy.

**OUTCOMES**
Outcomes may be better when helmet therapy is started before 6 mo
of age, and infants starting therapy later than that do not achieve the
same degree of normal head measurements as those whose helmet
therapy is started before 6 mo of age do. Significant improvements in
asymmetry are usually obvious at 4-11 wk after initiation of helmet
therapy.

Studies in patients with a median follow-up age of 9 yr old found
that 75% of cases had a what both parents and patients considered to
be a normal head appearance. Nine percent of patients and 4% of
parents noted residual asymmetry that they considered significant.

Cognitive and academic outcomes may be different depending on
the side of deformity. Poorer academic performance and greater speech
abnormalities were found in patients with left-sided deformities com-
pared to those with right-sided deformities. This manifested as double
the number of patients with expressive speech abnormalities and triple
the number of special education needs. It is unclear what the underly-
ing mechanism is; treatment differences were apparently not a factor.
In general, children with DP and without comorbid conditions are
usually developmentally normal, healthy children. This is in contrast
to craniosynostosis, in which increases in intracranial pressure may
have deleterious effects on central nervous system function.

*Bibliography is available at Expert Consult.*
A seizure is a transient occurrence of signs and/or symptoms resulting from abnormal excessive or synchronous neuronal activity in the brain. The International Classification of Epileptic Seizures divides epileptic seizures into 2 large categories: In focal (formerly known as partial) seizures, the first clinical and electroencephalographic (EEG) changes suggest initial activation of a system of neurons limited to part of 1 cerebral hemisphere. The term simple partial seizures is an outdated classification that refers to focal seizures with no alteration in consciousness whereas complex partial seizures, currently also referred to as focal dyscognitive, denote focal seizures with altered awareness of the surroundings. In generalized seizures, the first clinical and EEG changes indicate synchronous involvement of all of both hemispheres (Table 593-1). Approximately 30% of patients who have a first afebrile seizure have later epilepsy; the risk is approximately 20% if neurologic exam, EEG, and neuroimaging are normal. Febrile seizures are a separate category. Acute symptomatic seizures occur secondary to an acute problem affecting brain excitability such as electrolyte imbalance. Most children with these types of seizures do well. However, sometimes these seizures signify major structural, inflammatory, or metabolic disorders of the brain, such as meningitis, encephalitis, acute stroke, or brain tumor. Consequently, the prognosis depends on the underlying disorder, including its reversibility or treatability and the likelihood of developing epilepsy from it. An unprovoked seizure is one that is not an acute symptomatic seizure. Remote symptomatic seizure is one that is considered to be secondary to a distant brain injury, such as an old stroke. Reflex seizures are usually precipitated by a sensory stimulus such as flashing lights (see Chapter 593.9).

Epilepsy is a disorder of the brain characterized by an enduring predisposition to generate seizures and by the neurobiologic, cognitive, psychologic, and social consequences of this condition. The clinical diagnosis of epilepsy usually requires the occurrence of at least 1 unprovoked epileptic seizure with either a second such seizure or enough EEG and clinical information to convincingly demonstrate an enduring predisposition to develop recurrences. For epidemiologic and commonly for clinical purposes, epilepsy is considered to be present when 2 or more unprovoked seizures occur in a time frame of longer than 24 hr. Approximately 4-10% of children experience at least 1 seizure (febrile or afebrile) in the 1st 16 yr of life. The cumulative lifetime incidence of epilepsy is 3%, and more than half of the cases start in childhood. The annual prevalence is 0.5-1.0%. Thus, the occurrence of a single seizure or of febrile seizures does not necessarily imply the diagnosis of epilepsy. Seizure disorder is a general term that is usually used to include any 1 of several disorders, including epilepsy, febrile seizures, and possibly single seizures and symptomatic seizures secondary to metabolic, infectious, or other etiologies (e.g., hypocalcemia, meningitis).

An epileptic syndrome is a disorder that manifests 1 or more specific seizure types and has a specific age of onset and a specific prognosis. Several types of epileptic syndromes can be distinguished

(Tables 593-2 to 593-5). This classification has to be distinguished from the classification of epileptic seizures that refers to single events rather than to clinical syndromes. In general, seizure type is the primary determinant of the type of medications the patient is likely to respond to, and the epilepsy syndrome determines the type of prognosis one could expect. An epileptic encephalopathy is an epilepsy syndrome in which there is a severe EEG abnormality which is thought to result in cognitive and other impairments in the patient. Idiopathic epilepsy is an older term that refers to an epilepsy syndrome that is genetic or presumed genetic and in which there is no underlying disorder affecting development or other neurologic function (e.g., petit mal epilepsy). In the International League Against Epilepsy (ILAE) classification of etiology of epilepsy, idiopathic epilepsy was replaced by the term genetic epilepsy, which implies that the epilepsy syndrome is the direct result of a known or presumed genetic defect(s) in which the genetic defect is not causative of a brain structural or metabolic disorder other than the epilepsy. Symptomatic epilepsy is also an older term referring to an epilepsy syndrome caused by an underlying brain disorder that may or may not be genetic (e.g., epilepsy secondary to tuberous sclerosis or to an old stroke); this is referred to as structural/metabolic epilepsy, which would be caused by a distinct structural or metabolic entity that increases the risk for seizures and causes the epilepsy. The older terms of cryptogenic epilepsy or of presumed symptomatic epilepsy refer to an epilepsy syndrome in which there is a presumed underlying brain disorder causing the epilepsy and affecting neurologic function, but the underlying disorder is not known; this is referred to as the unknown epilepsy, designating that the underlying cause of the epilepsy is as yet unknown.

**EVALUATION OF THE FIRST SEIZURE**

Initial evaluation of an infant or child during or shortly after a suspected seizure should include an assessment of the adequacy of the airway, ventilation, and cardiac function, as well as measurement of temperature, blood pressure, and glucose concentration. For acute evaluation of the first seizure, the physician should search for potentially life-threatening causes of seizures such as meningitis, systemic sepsis, unintentional or nonaccidental intentional head trauma, and ingestion of drugs of abuse or accidental ingestion of drugs or of other toxins. The history should attempt to define factors that might have promoted the convulsion and to provide a detailed description of the seizure and the child's postictal state (see Chapter 593.9). Most parents vividly recall their child's initial convulsion and can describe it in detail.

The subsequent step in an evaluation is to determine whether the seizure has a focal onset or is generalized. Focal seizures may be characterized by motor or sensory symptoms, which could include forceful turning of the head and eyes to 1 side, unilateral clonic movements beginning in the face or extremities, or a sensory disturbance, such as paresthesias or pain localized to a specific area. Focal seizures in an adolescent or adult usually indicate a localized lesion, whereas these seizures during childhood are often, but not always, secondary to a...

EEG, electroencephalogram; GEFS+, generalized epilepsy with febrile seizures plus.

Febrile seizures are seizures that occur between the age of 6 and 60 mo with a temperature of 38°C (100.4°F) or higher, that are not the result of central nervous system infection or any metabolic imbalance, and that occur in the absence of a history of prior afebrile seizures. A simple febrile seizure is a primary generalized, usually tonic–clonic, attack associated with fever, lasting for a maximum of 15 min, and not recurrent within a 24-hr period. A complex febrile seizure is more prolonged (>15 min), is focal, and/or reoccurs within 24 hr. Febrile status epilepticus is a febrile seizure lasting longer than 30 min. Some use the term simple febrile seizure plus for those with recurrent febrile seizures within 24 hr. Most patients with simple febrile seizures have a very short postictal state and usually return to their baseline normal behavior and consciousness within minutes of the seizure.

Between 2% and 5% of neurologically healthy infants and children experience at least 1, usually simple, febrile seizure. Simple febrile seizures do not have an increased risk of mortality even though they are, understandably, concerning to the parents when they first witness them. Complex febrile seizures may have an approximately 2-fold long-term increase in mortality, as compared to the general population, over the subsequent 2 yr, probably secondary to coexisting pathology. There are no long-term adverse effects of having 1 or more simple febrile seizures. Compared with age-matched controls, patients with febrile seizures do not have any increase in the incidence of abnormalities of behavior, scholastic performance, neurocognitive function, or attention. Children who develop later epilepsy, however, might experience such difficulties. Febrile seizures recur in approximately 30% of those experiencing a first episode, in 50% after 2 or more episodes, and in 50% of infants younger than 1 yr old at febrile seizure onset. Several factors affect recurrence risk (Table 593-6). Although approximately 15% of children with epilepsy have had febrile seizures, only 2-7% of children who experience febrile seizures proceed to develop epilepsy later in life. There are several predictors of epilepsy after febrile seizures (Table 593-7).

**GENETIC FACTORS**
The genetic contribution to the incidence of febrile seizures is manifested by a positive family history for febrile seizures in many patients. In some families, the disorder is inherited as an autosomal dominant
trait, and multiple single genes that cause the disorder have been identified in such families. However, in most cases the disorder appears to be polygenic, and the genes predisposing to it remain to be identified. Identified single genes include FEB 1, 2, 3, 4, 5, 6, 7, 8, 9, and 10 genes on chromosomes 8q13-q21, 19p13.3, 2q24, 5q14-q15, 6q22-24, 18p11.2, 21q22, 5q34, 3p24.2-p23, and 3q26.2-q26.33. Only the function of FEB 2 is known: it is a sodium channel gene, SCN1A.

Almost any type of epilepsy can be preceded by febrile seizures, and a few epilepsy syndromes typically start with febrile seizures. These are generalized epilepsy with febrile seizures plus (GEFS+), severe myoclonic epilepsy of infancy (also called Dravet syndrome), and, in many patients, temporal lobe epilepsy secondary to mesial temporal sclerosis.

GEFS+ is an autosomal dominant syndrome with a highly variable phenotype. Onset is usually in early childhood and remission is usually in mid-childhood. It is characterized by multiple febrile seizures and by several subsequent types of afebrile generalized seizures, including generalized tonic–clonic, absence, myoclonic, atonic, or myoclonic astatic seizures with variable degrees of severity. A focal febrile seizures plus epilepsy variant, in which the seizures are focal rather than generalized, has also been described.

Dravet syndrome is the most severe of the phenotypic spectrum of febrile seizure-associated epilepsies. It constitutes a distinct entity in the onset of which is in infancy. Its onset is characterized by febrile and febrile unilateral ictonic seizures recurring every 1 or 2 mo. These early seizures are typically induced by fever, but they differ from the usual febrile convulsions in that they are more prolonged, are more frequent, are focal and come in clusters. Seizures subsequently start to occur with lower fevers and then without fever. During the 2nd yr of life, myoclonus, atypical absences, and partial seizures occur frequently and developmental delay usually follows. This syndrome is usually caused by a de novo mutation, although rarely it is inherited in an autosomal dominant manner. The mutated gene is located on 2q24-31 and encodes for SCN1A, the same gene mutated in GEFS+ spectrum. However, in Dravet syndrome the mutations lead to loss of function and thus to a more severe phenotype. There are several milder variants of Dravet syndrome that manifest some but not all of the above features and that are referred to as Dravet syndrome spectrum or Borderland. Mutations in other genes may also cause Dravet syndrome or GEFS+ phenotypes.

The majority of patients who had prolonged febrile seizures and encephalopathy after vaccination and who had been presumed to have suffered from vaccine encephalopathy (seizures and psychomotor regression occurring after vaccination and presumed to be caused by it) turn out to have Dravet syndrome mutations, indicating that their disease is caused by the mutation and not secondary to the vaccine. This has raised doubts about the very existence of the entity termed vaccine encephalopathy.

**EVALUATION**

Figure 593-1 delineates the general approach to the patient with febrile seizures. Each child who presents with a febrile seizure requires a detailed history and a thorough general and neurologic examination. Febrile seizures often occur in the context of otitis media, roseola and human herpesvirus (HHV) 6 infection, shigellosis, or similar infections, making the evaluation more demanding. In patients with febrile status, HHV-6B (more frequently) and HHV-7 infections were found to account for one-third of the cases. Several laboratory studies need to be considered in evaluating the patient with febrile seizures.

**Lumbar Puncture**

Meningitis should be considered in the differential diagnosis, and lumbar puncture should be performed for all infants younger than 6 mo of age who present with fever and seizure, or if the child is ill-appearing or at any age if there are clinical signs or symptoms of concern. A lumbar puncture is an option in a child 6-12 mo of age who is deficient in Haemophilus influenzae type b and Streptococcus pneumoniae immunizations or for whom immunization status is unknown. A lumbar puncture is an option in children who have been pretreated with antibiotics. In patients presenting with febrile status epilepticus in the absence of a central nervous system infection, a nontraumatic lumbar puncture rarely shows cerebrospinal fluid (CSF) pleocytosis (96% have <3 nucleated cells in the CSF) and the CSF protein and glucose are usually normal.

**Electroencephalogram**

If the child is presenting with the first simple febrile seizure and is otherwise neurologically healthy, an EEG need not normally be performed as part of the evaluation. An EEG would not predict the future recurrence of febrile seizures or epilepsy even if the result is abnormal. Spikes during drowsiness are often seen in children with febrile seizures, particularly those older than age 4 yr, and these do not predict later epilepsy. EEGs performed within 2 wk of a febrile seizure often have nonspecific slowing, usually posteriorly. Thus, in many cases, if an EEG is indicated, it is delayed until or repeated after more than 2 wk have passed. An EEG should, therefore, generally be restricted to special cases in which epilepsy is highly suspected, and, generally, it should be used to delineate the type of epilepsy rather than to predict its occurrence. If an EEG is done, it should be performed for at least 20 min in wakefulness and in sleep according to international guidelines to avoid misinterpretation and drawing of erroneous conclusions. At times, if the patient does not recover immediately from a seizure, then an EEG can help distinguish between ongoing seizure activity and a prolonged postictal period, sometimes termed a nonepileptic twilight state. EEG can also be helpful in patients who present with febrile status epilepticus because the presence of focal slowing present on the EEG obtained within 72 hr of the status has been shown to be highly associated with MRI evidence of acute hippocampal injury.

**Blood Studies**

Blood studies (serum electrolytes, calcium, phosphorus, magnesium, and complete blood count) are not routinely recommended in the work-up of a child with a first simple febrile seizure. Blood glucose should be determined in children with prolonged postictal obtundation or with poor oral intake (prolonged fasting). Serum electrolyte values may be abnormal in children after a febrile seizure, but this should be suggested by precipitating or predisposing conditions elicited in the history and reflected in abnormalities of the physical examination. If clinically indicated (e.g., in a history or physical examination...
suggesting dehydration), these tests should be performed. A low sodium level is associated with higher risk of recurrence of the febrile seizure within the following 24 hr.

**Neuroimaging**

A CT or MRI is not recommended in evaluating the child after a first simple febrile seizure. The work-up of children with complex febrile seizures needs to be individualized. This can include an EEG and neuroimaging, particularly if the child is neurologically abnormal. Approximately 11% of children with febrile status epilepticus are reported to have (usually) unilateral swelling of their hippocampus acutely, which is followed by subsequent long-term hippocampal atrophy. Whether these patients will ultimately develop temporal lobe epilepsy remains to be determined.

**TREATMENT**

In general, antiepileptic therapy, continuous or intermittent, is not recommended for children with 1 or more simple febrile seizures. Parents should be counseled about the relative risks of recurrence of febrile seizures and recurrence of epilepsy, educated on how to handle a seizure acutely, and given emotional support. If the seizure lasts for longer than 5 min, acute treatment with diazepam, lorazepam, or midazolam is needed (see Chapter 593.8 for acute management of seizures and status epilepticus). Rectal diazepam is often prescribed to be given at the time of reoccurrence of a febrile seizure lasting longer than 5 min (see Table 593-12 for dosing). Alternatively, buccal or intranasal midazolam may be used and is often preferred by parents. Intravenous benzodiazepines, phenobarbital, phenytoin, or valproate may be needed in the case of febrile status epilepticus. If the parents are very anxious concerning their child’s seizures, intermittent oral diazepam (0.33 mg/kg every 8 hr during fever) or intermittent rectal diazepam (0.5 mg/kg administered as a rectal suppository every 8 hr), can be given during febrile illnesses. Intermittent oral nitrazepam, clobazam, and clonazepam (0.1 mg/kg/day) have also been used. Such therapies help reduce, but do not eliminate, the risks of recurrence of febrile seizures. Other therapies have included continuous phenobarbital (4-5 mg/kg/day in 1 or 2 divided doses), and continuous valproate (20-30 mg/kg/day in 2 or 3 divided doses). In the vast majority of cases, it is not justified to use continuous therapy owing to the risk of side effects and lack of demonstrated long-term benefits, even if the recurrence rate of febrile seizures is expected to be decreased by these drugs.

Antipyretics can decrease the discomfort of the child but do not reduce the risk of having a recurrent febrile seizure, probably because the seizure often occurs as the temperature is rising or falling. Chronic antiepileptic therapy may be considered for children with a high risk for later epilepsy. Currently available data indicate that the possibility of future epilepsy does not change with or without antiepileptic therapy. Iron deficiency is associated with an increased risk of febrile seizures, and thus screening for that problem and treating it appears appropriate.

**593.2 Unprovoked Seizures**

Mohamad A. Mikati and Abeer J. Hani

**HISTORY AND EXAMINATION**

Acute evaluation of a first seizure includes assessment of vital signs and respiratory and cardiac function, and institution of measures to normalize and stabilize them as needed. Signs of head trauma, abuse, drug intoxication, poisoning, meningitis, sepsis, focal abnormalities, increased intracranial pressure, herniation, neurocognitive stigmata, brainstem dysfunction, and/or focal weakness should all be sought because they could suggest an underlying etiology for the seizure.

The history should also include details of the seizure manifestations, particularly those that occurred at its initial onset. These could give clues to the type and brain localization of the seizure. One should also probe for previous signs or symptoms of other seizures in the preceding weeks, or longer, that the parents may have overlooked and did not report. In some instances, if the events have been going on for a time and there is a question about their nature (e.g., sleep myoclonus vs seizures), then the family could video record the patient and make the video available to the healthcare provider. Having the parents imitate the seizure can also be helpful. Seizure patterns (e.g., clustering), precipitating conditions (e.g., sleep or sleep deprivation, television, visual patterns, mental activity, stress), exacerbating conditions (e.g., menstrual cycle, medications), frequency, duration, time of occurrence, and other characteristics need to be carefully documented (see Chapter 593.9). Parents often overlook, do not report, or underreport absence, complex partial, or myoclonic seizures. A history of personality change or symptoms of increased intracranial pressure can suggest an intracranial tumor. Similarly, a history of cognitive regression can suggest a degenerative or metabolic disease. Certain medications such as stimulants or antihistamines, particularly sedating ones, can precipitate seizures. A history of prenatal or perinatal distress or of developmental delay can suggest etiologic congenital or perinatal brain dysfunction. Details of the spells can suggest nonepileptic paroxysmal disorders that mimic seizures (see Chapter 594).

**DIFFERENTIAL DIAGNOSIS**

This involves consideration of nonepileptic paroxysmal events (see Chapter 594), determination of the seizure type, as classified by the new ILAE system (see Table 593-1) and consideration of potential underlying etiologies. Some seizures might begin with auras, which are sensory experiences reported by the patient and not observed externally. These can take the form of visual (e.g., flashing lights or seeing colors or complex visual hallucinations), somatosensory (tingling), olfactory, auditory, vestibular, or experiential (e.g., déjà vu, déjà vécu feelings) sensations, depending upon the precise localization of the origin of the seizures.

Motor seizures can be tonic (sustained contraction), clonic (rhythmic contractions), myoclonic (rapid shock-like contractions, usually <50 msec in duration, that may be isolated or may repeat but usually are not rhythmic), atomic, or astatic. Astatic seizures often follow myoclonic seizures and cause a very momentary loss of tone with a sudden fall. Atomic seizures, on the other hand, are usually longer and the loss of tone often develops more slowly. Sometimes it is difficult to distinguish among tonic, myoclonic, atomic, or astatic seizures based on the history alone when the family reports only that the patient “falls”; in such cases, the seizure may be described as a drop attack. Loss of tone or myoclonus in only the neck muscles results in a milder seizure referred to as a head drop. Tonic, clonic, myoclonic, and atomic seizures can be focal (including 1 limb or 1 side only), focal with secondary generalization, or primary generalized. Epileptic spasms (axial spasms, these terms being preferred over infantile spasms because they can occur beyond infancy) consist of flexion or extension of truncal and extremity musculature that is sustained for 1-2 sec, shorter than what is seen in tonic seizures, which last longer than 2 sec. Focal motor clonic and/or myoclonic seizures that persist for days, months, or even longer are termed epilepsy partialis continua.

Absence seizures are generalized seizures consisting of staring, unresponsiveness, and eye flutter lasting usually for few seconds. Typical absences are associated with 3 Hz spike–and–slow-wave discharges and with petit mal epilepsy, which has a good prognosis. Atypical absences are associated with 1–2 Hz spike–and–slow-wave discharges, and with head atonia and myoclonus during the seizures. They occur in Lennox-Gastaut syndrome, which has a poor prognosis. Juvenile absences are similar to typical absences but are associated with 4–5 Hz spike-and-slow waves and occur in juvenile myoclonic epilepsy. Seizure type and other EEG and clinical manifestations determine the type of epilepsy syndrome with which a particular patient is afflicted (Table 593-8; see Chapter 593.8 and 593.9).

Family history of certain forms of epilepsy, like benign neonatal seizures, can suggest the specific epilepsy syndrome. More often, however, different members of a family with a positive history of epilepsy have different types of epilepsy. Head circumference can indicate...
Bibliography

Grill MF, Ng YT: "Simple febrile seizures plus (SFS+)": more than one febrile seizure within 24 hours is usually okay, *Epilepsy Behav* 27:472–475, 2013.

Selected Epilepsy Syndromes by Age of Onset

**NEONATAL PERIOD**
- Benign familial neonatal seizures (BFNS)
- Early myoclonic encephalopathy (EME)
- Ohtahara syndrome

**INFANCY**
- Epilepsy of infancy with migrating focal seizures
- West syndrome
- Myoclonic epilepsy in infancy (MEI)
- Benign infantile seizures
- Benign familial infantile epilepsy
- Dravet syndrome
- Myoclonic encephalopathy in nonprogressive disorders

**CHILDHOOD**
- Febrile seizures plus (FS+; can start in infancy; this can be generalized [GEFS+] or with focal seizures)
- Early-onset benign childhood occipital epilepsy (Panayiotopoulos type)
- Epilepsy with myoclonic tonic (previously astatic) seizures
- Benign epilepsy with centrotemporal spikes (BCECTS)
- Late-onset childhood occipital epilepsy (Gastaut type)
- Autosomal dominant nocturnal frontal lobe epilepsy (AD-NFLE)
- Epilepsy with myoclonic absences
- Lennox-Gastaut syndrome
- Epileptic encephalopathy with continuous spike-and-wave during sleep (CSWS)
- Landau-Kleffner syndrome
- Childhood absence epilepsy (CAE)

**ADOLESCENCE–ADULT**
- Juvenile absence epilepsy (JAE)
- Juvenile myoclonic epilepsy (JME)
- Epilepsy with generalized tonic–clonic seizures alone
- Progressive myoclonus epilepsies (PME)
- Autosomal dominant epilepsy with auditory features (ADEAF)
- Other familial temporal lobe epilepsies

**AGE-RELATED (AGE OF ONSET LESS SPECIFIC)**
- Familial focal epilepsy with variable foci (childhood to adult)
- Reflex epilepsies

**SEIZURE DISORDERS THAT ARE NOT TRADITIONALLY GIVEN THE DIAGNOSIS OF EPILEPSY**
- Benign neonatal seizures (BNS)
- Febrile seizures (FS)

**EPILEPTIC ENCEPHALOPATHIES**
- EME
- Ohtahara syndrome
- Migrating partial seizures of infancy
- West syndrome
- Dravet syndrome
- Myoclonic encephalopathy in nonprogressive disorders
- Epilepsy with myoclonic astatic seizures
- Lennox-Gastaut syndrome
- Epileptic encephalopathy with CSWS
- Landau-Kleffner syndrome

**OTHER SECONDARY GENERALIZED EPILEPSIES**
- Generalized epilepsy secondary to neurodegenerative disease
- Progressive myoclonus epilepsies

The approach to the patient with epilepsy is based on the diagnostic scheme proposed by the ILAE Task Force on Classification and Terminology and presented in Table 593-9. This emphasizes the total approach to the patient, including identification, if possible, of the underlying etiology of the epilepsy and the impairments that result from it. The impairments are very often just as important as, if not more important than, the seizures themselves. Most epilepsy syndromes are potentially caused by any 1 of multiple underlying or still undetermined etiologies. However, in addition, there are many epilepsy syndromes that are associated with specific gene mutations.

**LONG-TERM APPROACH TO THE PATIENT AND ADDITIONAL TESTING**
- Electrocardiography (ECG) to rule out long QT or other cardiac dysrhythmias and other tests directed at disorders that could mimic seizures may be needed (see Chapter 594). EEG is highly recommended to assess for focal abnormalities and predict seizure recurrence.
myoclonic epilepsies, and to patients with syndromes of mendelian inheritance (see Table 593-2).

Patients with recurrent seizures, specifically with 2 seizures spaced apart by longer than 24 hr, warrant further work-up directed at the underlying etiology. In patients with drug-resistant epilepsy, or in infants with new-onset epilepsy in whom the initial testing did not reveal an underlying etiology, a full metabolic work-up, including amino acids, organic acids, biotinidase, and CSF studies, is needed. Additional testing can include, depending on the case, some or most of the following:

1. Measurement of serum lactate, pyruvate, acyl carnitine profile, creatine, very-long-chain fatty acids, and guanidino-acetic acid.
2. Blood and serum sometimes need to be tested for white blood cell lysosomal enzymes, serum coenzyme Q levels, and serum copper and ceruloplasmin levels (for Menkes syndrome).
3. Serum immune isoelectric focusing is performed for carbohydrate-deficient transferrin.
4. CSF glucose testing looks for glucose transporter deficiency, and CSF can be examined for cells and proteins (for parainfectious and postinfectious syndromes, and for Aicardi-Goutières syndrome, which also shows cerebral calcifications and has a specific gene defect test available).
5. Other laboratory studies include immunoglobulin (Ig) G index, NMDA (N-methyl-D-aspartate) receptor antibodies, and measles titers.
6. CSF tests can also confirm with, the appropriate clinical setup, the diagnosis of cerebral folate deficiency, pyridoxine dependency, pyridoxal dependency, mitochondrial disorders, nonketotic hyperglycinemia, nepotin/bioperin metabolism disorders, adenylosuccinate lyase deficiency, and neurotransmitter deficiencies. In infants who do not respond immediately to antiepileptic therapy, vitamin B6 (100 mg intravenously) is given as a therapeutic trial to help diagnose pyridoxine-responsive seizures, with precautions to guard against possible apnea. The trial is best done with continuous EEG monitoring, including a prednistration baseline recording period. Prior to the vitamin B6 trial, a pyridoxal level and urine and CSF α-aminoacidic acid semialdehyde levels should be drawn, because they often elevated in this rare syndrome and the therapeutic trial result may not be definitive. Some patients are pyridoxal phosphate, rather than pyridoxine, dependent.

Also patients with cerebral folate deficiency can have intractable seizures. Thus trials of pyridoxal phosphate given orally (up to 50 mg/kg) and folic acid (up to 3 mg/kg) over several weeks can help diagnose these rare disorders while waiting for the definitive diagnosis from CSF or genetic testing for these disorders. Certain EEG changes such as continuous spike–and–slow-wave seizure activity and burst-suppression patterns may also suggest these vitamin-responsive syndromes.

7. Urine may also need to be tested for urinary sulfites indicating molybdodenum cofactor deficiency and for oligosaccharides and mucopolysaccharides. MR spectroscopy is performed for lactate and creatine peaks to rule out mitochondrial disease and creatine transporter deficiency.
8. Gene testing looks for specific disorders that can manifest with seizures, including SCN1A mutations in Dravet syndrome; ARX gene for West syndrome in boys; MECP2, CDKL5, and protocadherin 19 for Rett syndrome and similar presentations; syntxin binding protein for Ohtahara syndrome; and polymerease G for West syndrome and other seizures in infants. Gene testing can also be performed for other dyssorphic or metabolic syndromes.
9. Muscle biopsy can be performed for mitochondrial enzymes and coenzyme Q10 levels, and skin biopsy for inclusion bodies seen in neuronal ceroid lipofuscinosis and Lafora body disease is sometimes needed.
10. Genetic panels are available that include multiple genes that can cause epilepsy at specific ages; whole-exome sequencing is also available. These can be helpful in selected patients.

Most patients do not require a work-up anywhere near the above described extensive testing. The pace and extent of the work-up must depend critically upon the clinical epileptic and nonepileptic features, the family and antecedent personal history of the patient, the medication responsiveness of the seizures, the likelihood of identifying a treatable condition, and the wishes and need of the family to assign a specific diagnosis to the child's illness.

Bibliography is available at Expert Consult.

593.3 Partial Seizures and Related Epilepsy Syndromes

Mohamad A. Mikati and Abeer J. Hani

Partial (now referred to as focal) seizures account for approximately 40% of seizures in children and can be divided into simple partial seizures (currently referred to in the most recent ILAE classification as focal seizures without impairment of consciousness), in which consciousness is not impaired, and complex partial seizures (currently referred to as focal seizures with impairment of consciousness, also called focal dyssognitive seizures), in which consciousness is affected. Simple and complex partial seizures can each occur in isolation, one can temporally lead to the other (usually simple to complex), and/or each can progress into secondary generalized seizures (tonic, clonic, atonic, or most often tonic–clonic).

FOCAL SEIZURES WITHOUT IMPAIRMENT OF CONSCIOUSNESS

These can take the form of sensory seizures (auras) or brief motor seizures, the specific nature of which gives clues as to the location of the seizure focus. Brief motor seizures are the most common and include focal tonic, clonic, or atonic seizures. Often there is a motor (jacksonian) march from face to arm to leg, adversive head and eye movements to the contralateral side, or postictal (Todd) paralysis that can last minutes or hours, and sometimes longer. Unlike tics, motor seizures are not under partial voluntary control; seizures are more often stereotyped and less likely than tics to manifest different types in a given patient.

FOCAL SEIZURES WITH IMPAIRMENT OF CONSCIOUSNESS

These seizures usually last 1–2 min and are often preceded by an aura, such as a rising abdominal feeling, déjà vu or déjà vécu, a sense of fear, complex visual hallucinations, micropsia or macropsia (temporal lobe), generalized difficult-to-characterize sensations (frontal lobe), focal sensations (parietal lobe), or simple visual experiences (occipital lobe). Children younger than 7 yr old are less likely than older children to report auras, but parents might observe unusual preictal behaviors that suggest the experiencing of auras. Subsequent manifestations consist of decreased responsiveness, staring, looking around seemingly purposelessly, and automatism. Automatisms are automatic semipurposeful movements of the mouth (oral, alimentary such as chewing) or of the extremities (manual, such as manipulating the sheets; leg automatisms such as shuffling, walking). Often there is salivation, dilation of the pupils, and flushing or color change. The patient might appear to react to some of the stimulation around him or her but does not later recall the epileptic event. At times, walking and/or marked limb flailing and agitation occur, particularly in patients with frontal lobe seizures. Frontal lobe seizures often occur at night and can be very numerous and brief, but other complex partial seizures from other areas in the brain can also occur at night, too. There is often contralateral dystonic posturing of the arm and, in some cases, unilateral or bilateral tonic arm stiffening. Some seizures have these manifestations with minimal or no automatism. Others consist of altered consciousness with contralateral motor, usually clonic, manifestations. After the seizure, the patient can have postictal automatisms, sleepiness, and/or other transient focal deficits such as weakness (Todd paralysis) or aphasia.
Bibliography
SECONDARY GENERALIZED SEIZURES

Seizures of this type were previously known as focal seizures with impairment of consciousness evolving to bilateral convulsive seizures. Secondary generalized seizures can start with generalized clinical phenomena (from rapid spread of the discharge from the initial focus), or as simple or complex partial seizures with subsequent clinical generalization. There is often adverisive eye and head deviation to the side contralateral to the side of the seizure focus followed by generalized tonic, clonic, or tonic–clonic activity. Tongue biting, urinary and stool incontinence, vomiting with risk of aspiration, and cyanosis are common. Fractures of the vertebrae or humerus are rare complications. Most such seizures last 1-2 min. Tonic focal or secondary generalized seizures often manifest adverisive head deviation to the contralateral side, or fencing, hemi- or full figure-of-four arm, or Statue of Liberty postures. These postures often suggest frontal origin, particularly when consciousness is preserved during them, indicating that the seizure originated from the medial frontal supplementary motor area.

EEG in patients with focal/partial seizures usually shows focal spikes or sharp waves in the lobe where the seizure originates. A sleep-deprived EEG with recording during sleep increases the diagnostic yield and is advisable in all patients whenever possible (Fig. 593-2). Despite that, approximately 15% of children with epilepsy initially have normal EEGs because the discharges are relatively infrequent or the focus is deep. If repeating the test does not detect paroxysmal findings, then longer recordings in the laboratory or using ambulatory EEG or even inpatient 24-hr video EEG monitoring may be helpful. The latter is particularly helpful if the seizures are frequent enough, because it then can allow visualization of the clinical events and the corresponding EEG tracing.

Brain imaging is critical in patients with focal seizures. In general, MRI is preferable to CT, which misses subtle but occasionally potentially clinically significant lesions. MRI can show pathologies such as changes as a result of previous strokes or hypoxic injury, malformations, medial temporal sclerosis, arteriovenous malformations, inflammatory pathologies, or tumors (Fig. 593-3).

**BENIGN EPILEPSY SYNDROMES WITH FOCAL SEIZURES**

The most common such syndrome is benign childhood epilepsy with centrotemporal spikes which typically starts during childhood (ages 3-10 yr) and is outgrown in adolescence. The child typically wakes up at night owing to a focal (simple partial) seizure causing buccal and throat tingling and tonic or clonic contractions of 1 side of the face, with drooling and inability to speak but with preserved consciousness and comprehension. Dyscognitive focal (complex partial) and secondary generalized seizures can also occur. EEG shows typical broad-based centrotemporal spikes that are markedly increased in frequency during drowsiness and sleep. MRI is normal. Patients respond very well to antiepileptic drugs (AEDs) such as carbamazepine. In some patients who only have rare and mild seizures treatment might not be needed.

Benign epilepsy with occipital spikes can occur in early childhood (Panayiotopoulos type) and manifests with complex partial seizures with ictal vomiting, or they appear in later childhood (Gastaut type) with complex partial seizures, visual auras, and migraine headaches. Both are typically outgrown in a few years. Manifestations may include visual hallucinations and postictal headache (epilepsy–migraine sequence).

In infants, several less-common benign infantile familial convulsion syndromes have been reported. For some of these, the corresponding gene mutation and its function are known (see Tables 593-2 and 593-5), but for others, the genetic underpinnings are yet to be determined. Specific syndromes include benign infantile familial convulsions with parietooccipital foci linked to chromosomal loci 19q and 2q, benign familial infantile convulsions with associated choreoathetosis linked to chromosomal locus 16p12-q12, and benign

---

**Figure 593-2** A, Representative EEG associated with partial seizures: (i) Spike discharges from the left temporal lobe (arrow) in a patient with complex partial seizures caused by mesial temporal sclerosis; (ii) left central-parietal spikes (arrow) characteristic of benign partial epilepsy with centrotemporal spikes. B, Representative EEGs associated with generalized seizures: (i) 3/sec spike-and-wave discharge of absence seizures with normal background activity; (ii) 1-2/sec interictal slow spike waves in a patient with Lennox-Gastaut syndrome; (iii) hypsarrhythmia with an irregular multifocal high-voltage spike and wave activity with chaotic high-voltage slow background; (iv) juvenile myoclonic epilepsy EEG showing 4-6/sec spike and waves enhanced by photic stimulation.
infantile familial convulsions with hemiplegic migraine linked to chromosome 1. A number of benign infantile nonfamilial syndromes have been reported, including dyssynergic focal (complex partial) seizures with temporal foci, secondary generalized tonic–clonic seizures with variable foci, tonic seizures with midline foci, and partial seizures in association with mild gastroenteritis. All of these have a good prognosis and respond to treatment promptly, often necessitating only short-term (e.g., 6 mo), if any, therapy. Nocturnal autosomal dominant frontal lobe epilepsy has been linked to acetylcholine-receptor gene mutations and manifests with nocturnal seizures with dystonic posturing and agitation, screaming, kicking that respond promptly to carbamazepine. Several other less-frequent familial benign epilepsy syndromes with different localizations have also been described, some of which occur exclusively or predominantly in adults (see Table 593-2).

SEVERE EPILEPSY SYNDROMES WITH FOCAL SEIZURES

Symptomatic structural/metabolic epilepsy secondary to focal brain lesions has a higher chance of being severe and refractory to therapy than idiopathic genetic epilepsy. It is important to note that many patients with focal lesions, for example, old strokes or brain tumors, either never have seizures or have well-controlled epilepsy. In infants, drug-resistant epilepsy with focal seizures is often caused by severe metabolic problems, hypoxic–ischemic injury, or congenital malformations. In addition, in this age group, a syndrome of multifocal severe partial seizures with progressive mental regression and cerebral atrophy called migrating partial seizures of infancy has been described. In infants and older children, several types of lesions, which can occur in any lobe, can cause intractable epilepsy and seizures and some cases may be secondary to mutations in the calcium sensitive potassium channel KCNT1. Brain malformations causing focal epilepsy include focal cortical dysplasia, hemimegalencephaly, Sturge-Weber hemangioma, tuberous sclerosis, and congenital tumors such as ganglioglioma, and dysembryoplastic neuroepithelial tumors, as well as others. The intractable seizures can be simple partial, complex partial, secondary generalized, or combinations thereof. If secondary generalized seizures predominate and take the form of absence-like seizures and drop attacks, the clinical picture can mimic the generalized epilepsy syndrome of Lennox-Gastaut syndrome has and been termed by some pseudo–Lennox-Gastaut syndrome.

Temporal lobe epilepsy can be caused by any temporal lobe lesion. A common cause is mesial (also termed medial) temporal sclerosis, a condition often preceded by febrile seizures and, rarely, genetic in origin. Pathologically, these patients have atrophy and gliosis of the hippocampus and, in some, of the amygdala. It is the most common cause of surgically remediable partial epilepsy in adolescents and adults. Occasionally, in patients with other symptomatic or cryptogenic partial or generalized epilepsies, the focal discharges are so continuous that they cause an epileptic encephalopathy. Activation of temporal discharges in sleep can lead to loss of speech and verbal auditory agnosia (Landau-Kleffner epileptic aphasia syndrome). Activation of frontal and secondary generalized discharges in sleep leads to more global delay secondary to the syndrome of continuous spike waves in slow-wave sleep (>85% of slow-wave sleep recording dominated by discharges).

The syndrome of Rasmussen encephalitis is a form of chronic encephalitis that manifests with unilateral intractable partial seizures, epilepsy partialis continua, and progressive hemiparesis of the affected side, with progressive atrophy of the contralateral hemisphere. The etiology is usually unknown. Some cases have been attributed to cytomegalovirus and others to anti-NMDA receptor autoantibodies.

593.4 Generalized Seizures and Related Epilepsy Syndromes

Mohamad A. Mikati and Abeer J. Hani

ABSENCE SEIZURES

Typical absence seizures usually start at 5–8 yr of age and are often, owing to their brevity, overlooked by parents for many months even though they can occur up to hundreds of times per day. Unlike complex partial seizures they do not have an aura, usually last for only a few seconds, and are accompanied by eye lid flutter or upward rolling of the eyes but typically not by the usually more florid automatisms of complex partial seizures (absence seizures can have simple automatisms like lip-smacking or picking at clothing and the head can minimally fall forward). Absence seizures do not have a postictal period and are characterized by immediate resumption of what the patient was doing before the seizure. Hyperventilation for 3–5 min can precipitate the seizures and the accompanying 3 Hz spike–and–slow-wave
discharges. The presence of periorbital, lid, perioral or limb myoclonic jerks with the typical absence seizures usually predicts difficulty in controlling the seizures with medications. Early onset absence seizures (before the age of 4 yr) should trigger evaluation for glucose transporter defect that is often associated with low CSF glucose levels and an abnormal sequencing test of the transporter gene.

**Atypical absence seizures** have associated myoclonic components and tone changes of the head (head drop) and body and are also usually more difficult to treat. They are precipitated by drowsiness and are usually accompanied by 1-2 Hz spike- and- slow-wave discharges.

**Juvenile absence seizures** are similar to typical absences but occur at a later age and are accompanied by 4-6 Hz spike- and- slow-wave and polyspike- and- slow-wave discharges. These are usually associated with juvenile myoclonic epilepsy (see “Benign Generalized Epilepsies”).

**GENERALLIZED MOTOR SEIZURE**

The most common generalized motor seizures are generalized tonic-clonic seizures that can be either primarily generalized (bilateral) or secondarily generalized (as described in Chapter 593.3) from a unilateral focus. If there is no partial component, then the seizure usually starts with loss of consciousness and, at times, with a sudden cry, upward rolling of the eyes, and a generalized tonic contraction with falling, apnea, and cyanosis. In some, a clonic or myoclonic component precedes the tonic stiffening. The tonic phase is followed by a clonic phase that, as the seizure progresses, shows slowing of the rhythmic contractions until the seizure stops usually 1-2 min later. Incontinence and a postictal period often follow. The latter usually lasts for 30 min to several hours with semicoma or obtundation and postictal sleepiness, weakness, ataxia, hyper- or hyporeflexia, and headaches. There is a risk of aspiration and injury. First aid measures include positioning the patient on his or her side, clearing the mouth if it is open, loosening tight clothes or jewelry, and gently extending the head and, if possible, insertion of an airway by a trained professional. The mouth should not be forced open with a foreign object (this could dislodge teeth, causing aspiration) or with a finger in the mouth (this could result in serious injury to the examiner’s finger). Many patients have single idiopathic generalized tonic–clonic seizures that may be associated with intercurrent illness or with a cause that cannot be ascertained (see Chapter 593.2). Generalized tonic, atonic, and atactic seizures often occur in severe generalized pediatric epilepsies. Generalized myoclonic seizures can occur in either benign or difficult-to-control generalized epilepsies (see “Benign Generalized Epilepsies” and “Severe Generalized Epilepsies”).

**BENIGN GENERALIZED EPILEPSIES**

Petit mal epilepsy typically starts in mid-childhood, and most patients outgrow it before adulthood. Approximately 25% of patients also develop generalized tonic–clonic seizures, half before and half after the onset of absences. Benign myoclonic epilepsy of infancy consists of the onset of myoclonic and other seizures during the 1st yr of life, with generalized 3 Hz spike- and- slow-wave discharges. Often, it is initially difficult to distinguish this type from more-severe syndromes, but follow-up clarifies the diagnosis. Febrile seizures plus syndrome manifests febrile seizures and multiple types of generalized seizures in multiple family members, and at times different individuals within the same family manifest different generalized and febrile seizure types (see Chapter 593.1).

Juvenile myoclonic epilepsy (Janz syndrome) is the most common generalized epilepsy in young adults, accounting for 5% of all epilepsies. It has been linked to mutations in many genes including CACNB4; CLCN2; E2M2, 3, 4, 5, 6, 7, 9; GABRA1; GABRD; and Myoclonin1/EFHC1 (see Table 593-2). Typically, it starts in early adolescence with 1 or more of the following manifestations: myoclonic jerks in the morning, often causing the patient to drop things; generalized tonic–clonic or clonic–tonic–clonic seizures upon awakening; and juvenile absences. Sleep deprivation, alcohol (in older patients), and photic stimulation, or, rarely, certain cognitive activities can act as precipitants. The EEG usually shows generalized 4-5 Hz polyspike- and- slow-wave discharges. There are other forms of generalized epilepsies such as photoparoxysmal epilepsy, in which generalized tonic–clonic, absence or myoclonic generalized seizures are precipitated by photic stimuli such as strobe lights, flipping through TV channels and viewing video games. Other forms of reflex (i.e., stimulus-provoked) epilepsy can occur; associated seizures are usually generalized, although some may be focal (see Table 593-1 and Chapter 593.9).

**SEVERE GENERALIZED EPILEPSIES**

Severe generalized epilepsies are associated with intractable seizures and developmental delay. Early myoclonic infantile encephalopathy starts during the 1st 2 mo of life with severe myoclonic seizures and burst suppression pattern on EEG. It is usually caused by inborn errors of metabolism such as non-ketotic hyperglycinemia. Early infantile epileptic encephalopathy (Ohtahara syndrome) has similar age of onset and EEG but manifests tonic seizures and is usually caused by brain malformations or syntaxin binding protein 1 mutations. Severe myoclonic epilepsy of infancy (Dravet syndrome) starts as focal febrile status epilepticus or focal febrile seizures and later manifests myoclonic and other seizure types (see Chapter 593.1).

West syndrome starts between the ages of 2 and 12 mo and consists of a triad of infantile epileptic spasms that usually occur in clusters (particularly in drowsiness or upon arousal), developmental regression, and a typical EEG picture called hypsarrhythmia (see Fig. 593-2). Hypsarrhythmia is a high-voltage, slow, chaotic background with multifocal spikes. Patients with cryptogenic (sometimes called idiopathic, now referred to as unknown etiology) West syndrome have normal development before onset, while patients with symptomatic West syndrome have preceding developmental delay owing to perinatal encephalopathies, malformations, underlyng metabolic disorders, or other etiologies (see Chapter 593.2). In boys, West syndrome can also be caused by ARX gene mutations (often associated with ambiguous genitalia and cortical migration abnormalities). West syndrome, especially in cases of unknown etiology (cryptogenic cases, i.e., cases that are not symptomatic of metabolic or structural brain disorder), is a medical emergency because diagnosis delayed for 3 wk or longer can affect long-term prognosis. The spasms are often overlooked by parents and by physicians, being mistaken for startles caused by colic or for other benign paroxysmal syndromes (see Chapter 594).

Lennox-Gastaut syndrome typically starts between the ages of 2 and 10 yr and consists of a triad of developmental delay, multiple seizure types and that as a rule include atypical absences, myoclonic, atonic, and tonic seizures. The tonic seizures occur either in wakefulness (causing falls and injuries) or also, typically, in sleep. The third component is the EEG findings (see Fig. 593-2): 1-2 Hz spike- and- slow waves, polyspike bursts in sleep, and a slow background in wakefulness. Patients commonly have myoclonic, atonic, and other seizure types that are difficult to control, and most are left with long-term cognitive impairment and intractable seizures despite multiple therapies. Some, but not all, patients start with Ohtahara syndrome, develop West syndrome, and then progress to Lennox-Gastaut syndrome. Myoclonic atastic epilepsy is a syndrome similar to, but milder than, Lennox-Gastaut syndrome that usually does not have tonic seizures or polyspike bursts in sleep. The prognosis is more favorable than that for Lennox-Gastaut syndrome. Another syndrome characterized by atonic seizures causing head nodding as well as tonic, clonic and stimulus sensitive seizures is the nodding syndrome, which is a recently described epidemic type of epilepsy seen in some African countries and often associated with encephalopathy, stunted growth, and variable degrees of cognitive deficits. The underlying etiology is unknown.

Progressive myoclonic epilepsies are a group of epilepsies characterized by progressive dementia and worsening myoclonic and other seizures. Type I or Unverricht-Lundborg disease (secondary to a cystatin B mutation) is more slowly progressive than the other types and usually starts in adolescence. Type II or Lafora body disease can have an early childhood onset but usually starts in adolescence, is more quickly progressive, and is usually fatal within the 2nd or 3rd decade. It can be associated with photosensitivity, manifests periodic acid-Schiff-positive Lafora inclusions on muscle or skin biopsy (in eccrine-
sweat gland cells), and has been shown to be caused by laforin (EPM2A) or malin (EPM2B) gene mutations. Other causes of progressive myoclonic epilepsy include myoclonic epilepsy with ragged red fibers, sialidosis type 1, neuronal ceroid lipofuscinosis, juvenile neuropathic Gaucher disease, dentatorubral-pallidoluysian atrophy, and juvenile neuroaxonal dystrophy.

Myoclonic encephalopathy in nonprogressive disorders is an epileptic encephalopathy that occurs in some congenital disorders affecting the brain, such as Angelman syndrome, and consists of almost continuous and difficult-to-treat myoclonic and, at times, other seizures.

Landau-Kleffner syndrome is a rare condition of unknown cause characterized by loss of language skills attributed to auditory agnosia in a previously normal child. At least 70% have associated clinical seizures, but some do not. The seizures when they occur are of several types, including focal, generalized tonic–clonic, atypical absence, partial complex, and, occasionally, myoclonic seizures. High-amplitude spike-and-wave discharges predominate and tend to be bitemporal. In the later evolutionary stages of the condition, the EEG findings may be normal. The spike discharges are always more apparent during non–rapid eye movement sleep; thus, a child in whom Landau-Kleffner syndrome is suspected should have an EEG during sleep, particularly if the awake record is normal. CT and MRI studies typically yield normal results. In the related but clinically distinct epilepsy syndrome with continuous spike waves in slow-wave sleep, the discharges are more likely to be frontal or generalized and the delays more likely to be global. The approach and therapy to the 2 syndromes are similar. Valproic acid is often the anticonvulsant that is used first to treat the clinical seizures and may help the aphasia. Some children respond to clobazam, to the combination of valproic acid and clobazam, or to levetiracetam. For therapy of the aphasia, nocturnal diazepam therapy (0.2-0.5 mg/kg PO at bedtime for several months) is often used as first- or second-line therapy, as are oral steroids. Oral prednisone is started at 2 mg/kg/24 hr for 1 mo and decreased to 1 mg/kg/24 hr for an additional month. With clinical improvement, the prednisone is reduced further to 0.5 mg/kg/24 hr for up to 6-12 mo. Long-term therapy is often needed irrespective of what the patient responds to. If the seizures and aphasia persist after diazepam and steroids trials, then a course of intravenous immunoglobulins should be considered. It is imperative to initiate speech therapy and maintain it for several years, because improvement in language function occurs over a prolonged period.

Amenably treatable metabolic epilepsies are becoming increasingly recognized. Pyridoxine-dependent epilepsy typically presents as neonatal encephalopathy shortly after birth with, at times, report of increased fetal movements (seizure) in utero. There are associated gastrointestinal symptoms with emesis and abdominal distention, neuromyelitis optica-like irritability, sleepless and facial grimacing along with recurrent partial motor seizure, generalized tonic seizures, and myoclonus. Seizures are usually refractory and may progress to status epilepticus if no pyridoxine is used. Some cases start in infancy or in childhood. Diagnosis is confirmed by the presence of elevated plasma, urine and CSF α-aminoacidic semialdehyde and elevated plasma and CSF picolinic acid levels. The presence of either homozygous or compound heterozygous mutations in ALDH7A1 alleles (which encode the protein antithiokin) confirms the diagnosis. The use of pyridoxine 100 mg daily orally (up to 600 mg/day) or intravenously helps stop the seizures. Pyridoxal phosphate responsive neonatal epileptic encephalopathy (Pyridox[am]ine 5'-phosphate oxidase [PNPO] deficiency) may present similarly in the absence of gastrointestinal symptoms. Diagnostically, there are reduced pyridoxal phosphate levels in the CSF with increased levels of CSF levodopa and 3-methoxytyrosine along with decreased CSF homovanillic acid and 5-hydroxyindolacetic acid. The EEG may show a burst suppression pattern and treatment is by enteral administration of pyridoxal phosphate (up to 60 mg/kg/day). Folinic acid–responsive seizures may also present with neonatal epileptic encephalopathy and intractable seizures. These patients have a similar diagnostic profile as pyridoxine-dependent epilepsy patients and are caused by the same gene mutations but respond to folinic acid supplementation in addition to pyridoxine use. Cerebral folate deficiency, which also responds to high doses of folic acid (2-3 mg/kg/day), may manifest with epilepsy, intellectual disability, developmental regression, dyskinesias, and autism. CSF 5-methyltetrahydrofolate levels are decreased with normal plasma and red blood cell folate levels. There are usually mutations in the folate receptor (FOLR1) gene or blocking autoantibodies against membrane-associated folate receptors of the choroid plexus. Tetrahydrobiopterin deficiencies with or without hyperphenylalaninemia may present with epilepsies, and symptoms resulting from deficiencies of dopamine (parkinsonism, dystonia), noradrenaline (axial hypotonia), serotonin (depression, insomnia, temperature changes) and folate (myelin formation, basal ganglia calcifications, and seizures). Treatment is by substitution therapy with tetrahydrobiopterin and neurotransmitter precursors started as early as possible. Creatine deficiency syndromes present typically with developmental delay, seizures, autistic features, and movement disorders and are diagnosed by abnormal levels of urine creatine and guanidinoacetic acid and/or, depending on the type of underlying genetic etiology, with absent creatine peak on MR spectroscopy of the brain. Use of creatine monohydrate and dietary restrictions are helpful. Biotinidase deficiency presenting as developmental delay, seizures, ataxia, alopecia, and skin rash and often associated with intermittent metabolic acidosis and organic profile of lactic and propionic acidemia, responds to the use of biotin. Serum biosynthesis defects with low serine levels in plasma or CSF amino acids often present with congenital microcephaly, intractable seizures, and psychomotor retardation and respond to supplemental serine and glycine use. Developmental delay, epilepsy, and neonatal diabetes is caused by activating mutations in the adenosine triphosphate-sensitive potassium channels. Sulfonylurea drugs that block the potassium channel treat the neonatal diabetes and probably also favorably affect the central nervous system (CNS) symptoms and affect seizures. Hyperinsulinism–hyperammonemia syndrome is caused by activating mutations of the glutamate dehydrogenase encoded by the GLUD1 gene. Patients present with hypoglycemic seizures after a protein–rich meal with hyperammonemia (ammonia levels 80-150 μmol/L). They are managed with a combination of protein restriction, AEDs, and diazoxide (a potassium channel agonist that inhibits insulin release). GLUT-1 deficiency syndrome classically presents with infantile-onset epilepsy, developmental delay, acquired microcephaly, and complex movement disorders. It causes impaired glucose transport to the brain typically diagnosed by genetic testing or finding of low CSF lactate and CSF glucose, or low CSF to serum glucose ratios (less than 0.4). The manifestations of the disease are usually responsive to ketogenic diet.

593.5 Mechanisms of Seizures
Mohamad A. Mikati and Abeer J. Hani

One can distinguish in the pathophysiology of epilepsy 4 distinct, often sequential, mechanistic processes. First is the underlying etiology, which is any pathology or pathologic process that can disrupt neuronal function and connectivity and that eventually leads to the second process (epileptogenesis) which makes the brain epileptic. The underlying etiologies of epilepsy are diverse and include, among other entities, brain tumors and malformations, strokes, scarring, or mutations of specific genes. These mutations can involve voltage-gated channels (Na+, K+, Ca2+, Cl−, and HCN [hydrogen cyanide]), ligand-gated channels (nicotinic acetylcholine and γ-aminobutyric acid A receptors [GABAa]) or other proteins. In some but not in all such mutations, the molecular and cellular deficits caused by the mutations have been identified. For example, in Dravet syndrome, the loss of function mutation in the SCN1A gene causes decreased excitability in inhibitory GABAergic interneurons, leading to increased excitability and epilepsy. In human cortical dysplasia, the expression of the NR2B subunit of the NMDA receptor is increased, leading to excessive depolarizing currents. In many other epileptic conditions, a clear etiology is still lacking and in others the etiology may be known, but it is still not
known how the identified underlying genetic etiology or brain insult results in epileptogenesis.

Second, epileptogenesis is the mechanism through which the brain, or part of it, turns epileptic. The presence of this process explains why some patients with the above pathologies develop epilepsy and some do not. Kindling is an animal model for human focal epilepsy in which repeated electrical stimulation of selected areas of the brain with a low-intensity current initially causes no apparent changes but with repeated stimulation results in epilepsy. This repetitive stimulation can lead to a temporal lobe epilepsy, for example, through activation of metabotropic and ionotropic glutamate receptors (by glutamate), as well as the tropomyosin-related kinase B receptor (by brain-derived neurotrophic factor and neurotophin-4). This leads to an increase in the intraneuronal calcium, which, in turn, activates calcium calmodulin-dependent protein kinase and calcineurin, a phosphatase, resulting eventually in calcium-dependent epileptogenic gene expression (e.g., c-fos) and promotion of mossy fiber sprouting. Mossy fibers are excitatory fibers that connect the granule cells to the CA3 region within the hippocampus, and their pathologic sprouting underlies increased excitability in medial temporal lobe epilepsy associated with mesial temporal sclerosis in humans and in animal models. The cell loss in the CA3 region that is a characteristic of mesial temporal sclerosis (presumably resulting from an original insult such as a prolonged febrile status epilepticus episode or hypoxia) leads to a pathologic attempt at compensation by sprouting of the excitatory mossy fibers. Consequently, mossy fiber sprouting, which has been demonstrated in humans also, leads to increased excitability and to epilepsy. Complex febrile seizures in rats induce hyperactivation of, paradoxically excitatory, GABA$_{\text{A}}$ receptors leading to granule cell ectopia and to subsequent temporal lobe epilepsy. Possibly similar yet to be fully characterized epileptogenesis mechanisms may underlie other focal epilepsies.

Lately, the role of large-scale molecular cell signaling pathways in epileptogenesis, namely the mammalian target of rapamycin (mTOR), the Ras/ERK, and repressor element 1 (RE1)-silencing transcription factor (REST; also known as neuron-restrictive silencer factor) pathways have been implicated in the mechanisms leading to epilepsy. mTOR pathways in tuberous sclerosis, hemimegalencephaly and cortical dysplasia-related epilepsies, Ras/ERK in a number of syndromes, and REST in epilepsygenesis after acute neuronal injury.

The third process is the resultant epileptic state of increased excitability that is present in all patients irrespective of the underlying etiology or mechanism of epileptogenesis. In a seizure focus, each neuron has a stereotypic synchronized response called paroxysmal depolarization shift that consists of a sudden depolarization phase, resulting from glutamate and calcium channel activation, with a series of action potentials at its peak followed by an after-hyperpolarization phase, resulting from activation of potassium channels and GABA receptors that open chloride channels. When the after-hyperpolarization is disrupted in a sufficient number of neurons, the inhibitory surround is lost and a population of neurons fire at the same rate and time, resulting in a seizure focus. In childhood absence epilepsy, the discharging neurons also develop a paroxysmal depolarization shift similar to the one found in partial epilepsy. However, the mechanism of paroxysmal depolarization shift generation is different because it involves thalamocortical connections bilaterally. T-type calcium channels on thalamic relay neurons are activated during hyperpolarization by GABAergic interneurons in the reticular thalamic nucleus, which results in enhancement of synchronization in the thalamocortical loop and consequently in the typical generalized spike-wave pattern. In tumor-related epilepsy, particularly in that related to oligodendroglioma, the voltage-gated sodium channels are present on the surface of tumor cells at a higher density than on normal cells, and their inactivation is impaired by the alkaline pH present in this condition. In hypothalamic hamartoma causing gelastic seizures, clusters of GABAeric interneurons spontaneously fire, thus synchronizing the output of the hypothalamic hamartoma neurons projecting to the hippocampus.

The fourth process is seizure-related neuronal injury as demonstrated by MRI in patients after prolonged febrile and afebrile status epilepticus. Many such patients show acute swelling in the hippocampus and long-term hippocampal atrophy with sclerosis on MRI. Nonetheless in most patients with seizure-related MRI abnormalities, the findings are transient. In experimental models, the mechanisms of such injuries have been shown to involve both apoptosis and necrosis of neurons in the involved regions. There is evidence from surgically resected epileptic tissue that apoptotic pathways are activated in foci of intractable epilepsy.

In infantile spasms, recently developed animal models suggest that increases in stress-related corticotropin-releasing hormone, sodium channel blockade, and NMDA receptor stimulation are contributing mechanisms. Prior positron emission tomography data suggest that an interaction between focal cortical lesions and the brainstem raphe nuclei is important at least in some infantile spasms patients.

Bibliography is available at Expert Consult.

593.6 Treatment of Seizures and Epilepsy

Mohamad A. Mikati and Abeer J. Hani

DECIDING ON LONG-TERM THERAPY

After a first seizure, if the risk of recurrence is low, such as when the patient has normal neurodevelopmental status, EEG, and MRI (risk approximately 20%), then treatment is usually not started. If the patient has abnormal EEG, MRI, development, and/or neurologic exam, and/or a positive family history of epilepsy, then the risk is higher and often treatment is started. Other considerations are also important, such as motor vehicle driving status and type of employment in older patients or the parents’ ability to deal with recurrences or AED drug therapy in children. The decision is therefore always individualized. All aspects of this decision-making process should be discussed with the family. Figure 593-4 presents an overview of the approach to the treatment of seizures and epilepsy.

COUNSELING

An important part of the management of a patient with epilepsy is educating the family and the child about the disease, its management, and the limitations it might impose and how to deal with them. It is important to establish a successful therapeutic alliance. Restrictions on driving (in adolescents) and on swimming are usually necessary (Table 593-10). In most states, the physician is not required to report the epileptic patient to the motor vehicle registry; this is the responsibility of the patient. The physician then is requested to complete a specific form for patients who are being cleared to drive. Also in most states, a seizure-free period of 6 mo, and in some states longer, is required before driving is allowed. Often swimming in rivers, lakes, or sea, and underwater diving are prohibited, but swimming in swimming pools may be allowable. When swimming, even patients with epilepsy that is under excellent control should be under the continuous supervision of an observer who is aware of their condition and capable of lifeguard-level rescue.

The physician, parents, and child should jointly evaluate the risk of involvement in athletic activities. To participate in athletics, proper medical management, good seizure control, and proper supervision are crucial to avoid significant risks. Any activity where a seizure might cause a dangerous fall should be avoided; these activities include rope climbing, use of the parallel bars, and high diving. Participation in collision or contact sports depends on the patient’s condition. Epileptic children should not automatically be banned from participating in hockey, baseball, basketball, football, or wrestling. Rather, individual consideration should be based on the child’s specific case (see Table 593-10). Counseling is helpful to support the family and to educate them about the resources available in the community. Educational and, in some cases, psychologic evaluation may be necessary to evaluate for possible learning disabilities or abnormal behavioral patterns that might coexist with the epilepsy. Epilepsy does carry a risk of increased
Bibliography

mortality (2 or more times the standardized mortality rates of the general population) and of sudden unexpected death. This is mostly related to the conditions associated with or underlying the epilepsy (e.g., tumor, metabolic diseases), to poor seizure control (e.g., in patients with severe epileptic encephalopathies, or drug-resistant seizures), and to poor compliance with prescribed therapies. Thus, family members can usually be informed about this increased risk without inappropriately increasing their anxiety. Many family members feel they need to observe the patient continuously in wakefulness and sleep and have the patient sleep in the parents’ room to detect seizures. There are currently advertised seizure-detection equipment that use motion sensors placed under the mattress to detect seizures. Some are disappointing and ineffective in detecting seizures, whereas data from other equipment are encouraging in that they were useful in detecting a majority of generalized tonic–clonic seizures during sleep (see bibliography for details). Whether such measures can reduce sudden unexpected death in epilepsy (SUDEP) risk remains to be seen and the parents need to guard against being overprotective to avoid adversely affecting the psychology of the child. Education about what to do in case of seizures, the choices of treatment or no treatment and of medications and their side effects, and potential complications of epilepsy should be provided to the parents and, if the child is old enough, to the child.

**MECHANISMS OF ACTION OF ANTIEPILEPTIC DRUGS**

AEDs reduce excitability by interfering with the sodium, potassium or calcium ion channels, by reducing excitatory neurotransmitter release.
or function, or by enhancing GABAergic inhibition (Fig. 593-5). Most medications have multiple mechanisms of action, and the exact mechanism responsible for their activity in human epilepsy is usually not fully understood. Often, medications acting on sodium channels are effective against partial seizures, and medications acting on T-type calcium channels are effective against absence seizures. Voltage-gated sodium channels are blocked by felbamate, valproate, topiramate, carbamazepine, oxcarbazepine, lamotrigine, phenytoin, rufinamide, lacosamide, and zonisamide. T-type calcium channels, found in the thalamus area, are blocked by valproate, zonisamide, and ethosuximide. Voltage-gated calcium channels are inhibited by gabapentin, pregabalin, lamotrigine, and valproate. N-type calcium channels are inhibited by levetiracetam. Ezogabine/retigabine opens KCNQ/Kv7 voltage-gated potassium channels.

GABA\textsubscript{A} receptors are activated by phenobarbital, benzodiazepines, topiramate, felbamate, and levetiracetam. Tiagabine, by virtue of its binding to GABA transporters 1 (GAT-1) and 3 (GAT-3), is a GABA reuptake inhibitor. GABA levels are increased by vigabatrin via its irreversible inhibition of GABA transaminases. Valproate inhibits GABA transaminases, acts on GABA\textsubscript{B} presynaptic receptors (also done by gabapentin), and activates glutamic acid decarboxylase (the enzyme that forms GABA).

Glutaminergic transmission is decreased by felbamate that blocks NMDA and AMPA (\(\alpha\)-amino-3-hydroxy-5-methyl-4-isoxazole-propionic acid)/kainate receptors. Topiramate also blocks AMPA/kainate receptors. Levetiracetam also blocks AMPA/kainate receptors. Levetiracetam binds to the presynaptic vesicle protein SV2A found in all neurotransmitter vesicles and possibly results in inhibition of presynaptic neurotransmitter release in a use-dependent manner. Perampanel blocks glutamate AMPA receptors.

**CHOICE OF DRUG ACCORDING TO SEIZURE TYPE AND EPILEPSY SYNDROME**

Drug therapy should be based on the type of seizure and the epilepsy syndrome as well as on other individual factors. In general, the **drugs of first choice** for focal seizures and epilepsies are oxcarbazepine and carbamazepine; for absence seizures, ethosuximide; for juvenile myoclonic epilepsy, valproate and lamotrigine; for Lennox-Gastaut syndrome, clobazam, valproate, topiramate, lamotrigine, and, most recently, as add on, rufinamide; and for infantile spasms, adrenocorticotropic hormone (ACTH). There is significant controversy about these choices, and therapy should always be individualized (see **Choice of Drug: Other Considerations** below and Table 593-10).

**West syndrome** is best treated with ACTH. There are several protocols that range in dose from high to intermediate to low. The recommended regimen of ACTH (80 mg/mL) is a daily dose of 150 units/m\(^2\) (divided into twice-daily intramuscular injections of 75 units/m\(^2\), the lot number is recorded) administered over a 2-wk period with a subsequent gradual taper over a 2-wk period (30 units/m\(^2\) in the morning...
Very rare cases of patients who have neonatal, infantile, or early childhood seizures who have pyridoxine-dependent epilepsy (demonstrated to be caused by antiqtin gene mutation) respond to pyridoxine 10-100 mg/day orally (up to 600 mg/day has been used) within 3-7 days of the initiation of oral therapy and almost immediately if given parenterally. Some patients have seizures that are intractable from onset, but others have seizures that show an initial but transient response to traditional AEDs. Some of these patients also require concurrent folinic acid (5-15 mg/day). Other patients require the active form of vitamin B6, specifically, pyridoxal phosphate (50 mg/day initial dose that can be increased gradually up to 15 mg/kg every 6 hr) owing to their deficiency of PNPO. In both the PNPO-deficient/pyridoxal phosphate–dependent and the pyridoxine-dependent forms, hypotonia and hypopnea can occur after initiation of vitamin therapy. Pyridoxine has also been used by some, specifically in Japan, in the treatment of West syndrome. Patients with cerebral folate deficiency can respond to folinic acid supplementation (usually at doses of 2-3 mg/kg/day). Traditionally these entities have been diagnosed by giving the vitamin B6 or folinic acid in therapeutic trials, but currently laboratory testing is available to confirm the diagnosis (see Chapter 593.4).

Absence seizures are most often initially treated with ethosuximide, which is, as effective as, but less toxic than, valproate and more effective than lamotrigine. Alternative drugs of first choice are lamotrigine and valproate, especially if generalized tonic–clonic seizures coexist with absence seizures, as these 2 medications are effective against the latter seizures whereas ethosuximide is not. Patients resistant to ethosuximide might still respond to valproate or to lamotrigine. In absence seizures, the EEG is usually helpful in monitoring the response to therapy and is often more sensitive than the parents’ observations in detecting these seizures. The EEG often normalizes when complete seizure control is achieved. This is usually not true for partial epilepsies. Other medications that could be used for absence seizures include acetazolamide, zonisamide, or clonazepam.

Benign myoclonic epilepsies are often best treated with valproate, particularly when patients have associated generalized tonic–clonic and absence seizures. Benzodiazepines, clonazepam, lamotrigine, and topiramate are alternatives for the treatment of benign myoclonic epilepsy. Severe myoclonic epilepsies are treated with medications effective for Lennox-Gastaut syndrome such topiramate, clobazam, and valproate, as well as zonisamide. Levetiracetam may also have efficacy in myoclonic epilepsies.

Partial and secondary generalized tonic and clonic seizures can be treated with oxcarbazepine, levetiracetam, carbamazepine, phenobarbital, topiramate, valproic acid, lamotrigine, clobazam, or clonazepam (see Table 593-8). Oxcarbazepine, levetiracetam, carbamazepine (United States), or valproate (Europe) are often being used first. One study favored lamotrigine as initial monotherapy for partial seizures whereas ethosuximide is not. Patients resistant to ethosuximide should not be started until the metabolic disorders are ruled out and/or have metabolic disorders. Thus, if metabolic disorders are suspected, other drugs should be considered first and valproate should not be started until the metabolic disorders are ruled out by normal amino acids, organic acids, acylcarnitine profile, lactate,
ILAE recommendations are listed according to levels of evidence supporting the efficacy of the options. *ILAE recommendations are listed according to levels of evidence supporting the efficacy of the options. Level A: ≥1 class I randomized controlled trial (RCT) or ≥2 class II RCTs; Level B: 1 class II RCT or ≥2 class III RCTs; Level C: ≥2 class III RCTs; Level D: 1 class III double-blind or open-label study or 1 class IV clinical study or data from expert committee reports, opinions from experienced clinicians.

Pyruvate, liver function tests, and perhaps other tests. The choice of an AED can also be influenced by the likelihood of occurrence of nuisance side effects such as weight gain (valproate, carbamazepine), gingival hyperplasia (phenytoin), alopecia (valproate), hyperactivity (benzodiazepines, barbiturates, levetiracetam, valproate, gabapentin). Children with behavior problems and/or with attention-deficit disorder can become particularly hyperactive with GABAergic drugs mentioned above. This often affects the choice of medications.

**Ease of initiation** of the AED: Medications that are started very gradually such as lamotrigine and topiramate should not be chosen in situations when there is a need to achieve a therapeutic level quickly. In such situations, medications that have intravenous preparations or that can be started and titrated more quickly, such as valproate, phenytoin, or levetiracetam, should be considered instead.

**Drug interactions** and presence of background medications: An example is the potential interference of enzyme-inducing drugs with many chemotherapeutic agents. In those cases, medications like gabapentin or levetiracetam are used. Also, valproate inhibits the metabolism and increases the levels of lamotrigine, phenobarbital, and felbamate. It also displaces protein-bound phenytoin from protein-binding sites, increasing the free fraction, and, thus, the free and not the total level needs to be checked when both medications are being used together. Enzyme inducers like phenobarbital, carbamazepine, phenytoin, and primidone reduce levels of lamotrigine, valproate, and, to a lesser extent, topiramate and zonisamide. Medications exclusively excreted by the kidney like levetiracetam and gabapentin are not subject to such interactions.
The presence of comorbid conditions: For example, the presence of migraine in a patient with epilepsy can lead to the choice of a medication that is effective against both conditions such as valproate or topiramate. In an obese patient, a medication such as valproate might be avoided, and a medication that decreases appetite such as topiramate might be used instead. In adolescent girls of child-bearing potential, enzyme-inducing AEDs are often avoided because they can interfere with birth control pills; other AEDs, particularly valproate, can increase risks for fetal malformations (Table 593-12). Valproic acid may unmask or exacerbate certain underlying metabolic disorders; these include nonketotic hyperglycinemia, DNA polymerase \( \gamma \) mutations (PDE7), with mitochondrial DNA depletion (also known as Alpers-Huttenlocher syndrome), other mitochondrial disorders (Leigh syndrome; mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke-like episodes [MELAS]; myoclonic epilepsy with ragged red fibers; myoclonic epilepsy-myopathy-sensory ataxia syndrome), and hyperammonemnic encephalopathies. Manifestations may include hepatotoxicity or encephalopathy.

Coexisting seizures: In a patient with both absence and generalized tonic–clonic seizures, a drug that has a broad spectrum of antiseizure effects such as lamotrigine or valproate could be used rather than medications that have a narrow spectrum of efficacy, such as phenytoin and ethosuximide.

History of prior response to specific AEDs: For example, if a patient or a family member with the same problem had previously responded to carbamazepine, carbamazepine could be a desirable choice.

Mechanism of drug actions: At present, the current understanding of the pathophysiology of epilepsy does not allow specific choice of AEDs based on the assumed pathophysiology of the epilepsy. However, in general, it is believed that it is better to avoid combining medications that have similar mechanisms of action, such as phenytoin and carbamazepine (both work on sodium channels). A number of medications, such as lamotrigine and valproate or topiramate and lamotrigine, are reported to have synergistic effects, possibly because they have different mechanisms of action.

Ease of use: Medications that are given once or twice a day are easier to use than medications that are given 3 or 4 times a day. Availability of a pediatric liquid preparation, particularly if palatable, also plays a role.

Ability to monitor the medication and adjust the dose: Some medications are difficult to adjust and to follow, requiring frequent blood levels. The prototype of such medications is phenytoin, but many of the older medications also require blood level monitoring for optimal titration. However, monitoring in itself can represent a practical or patient satisfaction disadvantage for the older drugs as compared to the newer AEDs, which generally do not require blood-level monitoring except to check for compliance.

Patient's and family's preferences: All things being equal, the choice between 2 or more acceptable alternative AEDs might also depend on the patient's or family's preferences. For example, some patients might want to avoid gingival hyperplasia and hirsutism as side effects but might tolerate weight loss, or vice versa.

Genetics and genetic testing: A genetic predisposition to developing AED-induced side effects is another factor that may be a consideration. For example, there is a strong association between the human leukocyte antigen HLA-B\(^{1502}\) allele and severe cutaneous reactions induced by carbamazepine, phenytoin, or lamotrigine in Chinese Han patients and, to a lesser extent, South East Asian populations; hence these AEDs should be avoided in genetically susceptible persons after testing for the allele. The testing for other alleles that predispose to such allergies in other populations is not yet clinically useful. Mutations of the SCN1A sodium channel gene indicating Dravet syndrome could also lead to avoiding lamotrigine, carbamazepine, and phenytoin, and to the use of the more appropriate valproate, clobazam, or stiripentol.

Levels of recommendation: A: strongest recommendation; based on class 1 evidence; B and C: lower levels of recommendations.

Teratogenes and perinatal outcomes: AED polytherapy, as compared to monotherapy, regimens probably contribute to the development of major congenital malformations and adverse cognitive outcomes. Levels of recommendation: A: strongest recommendation; based on class 1 evidence; B and C: lower levels of recommendations.
**Teratogenic profiles**: Some AEDs, including valproate and to a lesser extent carbamazepine, phenobarbital, and phenytoin, are associated with teratogenic effects (see Table 593-12).

Some of these considerations can be addressed by resorting to expert opinion surveys (see Table 593-11) or to guidelines developed by concerned societies such as the ILAE, National Institute for Clinical Excellence (NICE) in England, Scottish Intercollegiate Guidelines Network (SIGN), or the American Academy of Neurology (AAN). Some guidelines are totally evidence based (AAN, ILAE), and others (NICE, SIGN) incorporate other considerations as well. However, no guideline is able to incorporate all the considerations relevant to each patient.

**INITIATING AND MONITORING THERAPY**

In nonemergency situations, or when loading is not necessary, the **maintenance dose** of the chosen AED is started (Table 593-13). With some medications (e.g., carbamazepine and topiramate), even smaller doses are initially started then **gradually increased** up to the maintenance dose to build tolerance to adverse effects such as sedation. For example, the starting dose of carbamazepine is usually 5-10 mg/kg/day. Increments of 5 mg/kg/day can be added every 3 days until a therapeutic level is achieved and a therapeutic response is established or until unacceptable adverse effects occur. With other medications such as zonisamide, phenobarbital, phenytoin, or valproate, starting at the maintenance dose is usually tolerated. With some, such as levetiracetam and gabapentin, either approach can be used. Patients should be counseled about potential adverse effects, and these should be monitored during follow-up visits (Table 593-14).

**Titration**

**Levels** of many AEDs should usually be determined after initiation to ensure compliance and therapeutic concentrations. Monitoring is most helpful for the older AEDs such as phenytoin, carbamazepine, valproate, phenobarbital, and ethosuximide. After starting the maintenance dosage or after any change in the dosage, a steady state is not reached until 5 half-lives have elapsed, which, for most AEDs, is 2-7 days (half-life: 6-24 hr). For phenobarbital, it is 2-4 wk (mean half-life: 69 hr). For zonisamide it is 14 days during monotherapy and less than that during polytherapy with enzyme inducers (half-life: 63 hr in monotherapy and 27-38 hr during combination therapy with enzyme inducers). If a therapeutic level has to be achieved faster, a **loading dose** may be used for some drugs, usually with a single dose that is twice the average maintenance dose per half-life. For valproate it is 25 mg/kg, for phenytoin it is 20 mg/kg, and for phenobarbital it is 10-20 mg/kg. A lower loading dosage of phenobarbital is sometimes given in older children (5 mg/kg, which may be repeated once or more in 24 hr), to avoid excessive sedation.

Only 1 drug should be used initially and the dose increased until complete control is achieved or until side effects prohibit further increases. Then, and only then, may another drug be added and the initial drug subsequently tapered. Control with 1 drug (monotherapy) should be the goal, although some patients eventually need to take

Unless specified otherwise, as above, one would usually target the lower range of therapeutic dose then adjust as needed depending on response and/or levels.

Dosing schedule (e.g., bid or tid) can depend on if a sustained release preparation is available and if the patient is on enzyme inducers (e.g., carbamazepine) or inhibitors (e.g., valproic acid) that could affect that drug (as indicated in the dosing in the table and in the text).

*Usually start by one-fourth maintenance dose and increase by one-fourth every 2-3 days to full dose.

</thead>
</table>
| Acetazolamide      | Nuisance: dizziness, polyuria, electrolyte imbalance  
                    | Serious: Stevens-Johnson syndrome |
| Benzodiazepines    | Nuisance: dose-related neurotoxicity (drowsiness, sedation, ataxia), hyperactivity, drooling, increased secretions  
                    | Serious: psychosis, rash, toxicity developing slowly owing to the very long half-life |
| Bromide            | Nuisance: irritability, spurious hyperchloremia (falsely high chloride owing to bromide)  
                    | Serious: psychosis, rash, toxicity developing slowly owing to the very long half-life |
| Carbamazepine      | Nuisance: dizziness, somnolence tremor, abnormal coordination, disturbance in attention, memory impairment, blurred vision, gait disturbance, and dysarthria  
                    | Serious: Stevens-Johnson syndrome, agranulocytosis, aplastic anemia, liver toxicity |
| Ezogabine          | Nuisance: dizziness, somnolence tremor, abnormal coordination, disturbance in attention, memory impairment, blurred vision, gait disturbance, and dysarthria  
                    | Serious: blue discoloration of the skin and retinal pigmentation that requires close ophthalmologic monitoring in follow up, urinary retention |
| Felbamate          | Nuisance: anorexia, vomiting, insomnia, hyperactivity, dizziness  
                    | Serious: major risks for liver and hematologic toxicity requiring close monitoring (1 in 500 in children >2 yr with complex neurological disorders) |
| Gabapentin         | In children: acute onset of aggression, hyperactivity  
                    | In adults: euphoria and behavioral disinhibition, weight gain |
| Lacosamide         | Nuisance: diplopia, headache, dizziness, nausea  
                    | Serious: possibly cardiac arrhythmias (if predisposed) |
| Lamotrigine        | Nuisance: CNS side effects: headache, ataxia, dizziness, tremor, but usually less than other AEDs  
                    | Serious: Stevens-Johnson syndrome, rarely liver toxicity |
| Levetiracetam      | CNS adverse events: somnolence, asthenia, dizziness, but usually less than other AEDs  
                    | In children: behavioral symptoms are common  
                    | In adults: depressive mood |
| Oxcarbazepine      | Somnolence, headache, dizziness, nausea, apathy, rash, hypertrichosis, gingival hypertrophy, hyponatremia |
| Perampanel         | Dizziness, somnolence, fatigue, irritability, falls, nausea, weight gain, vertigo, ataxia, gait disturbance, and balance disorder |
| Phenobarbital and  | Nuisance: neurotoxicity, insomnia, hyperactivity, signs of distractibility, fluctuation of mood, aggressive outbursts  
other barbiturates  | Serious: liver toxicity, Stevens-Johnson syndrome |
| Phenytoin and other | Nuisance: gingival hyperplasia, coarsening of the facies, hirsutism, cerebellovestibular symptoms (nystagmus and ataxia)  
hydantoins         | Serious: Stevens-Johnson syndrome, liver toxicity |
| Pregabalin         | Nuisance: dizziness, peripheral edema, blurred vision, weight gain, thrombocytopenia  
                    | Serious: hypersensitivity reactions, rhabdomyolysis |
| Primidone          | Nuisance: CNS toxicity (dizziness, slurred speech, giddiness, drowsiness, depression)  
                    | Serious: liver toxicity, Stevens-Johnson syndrome |
| Rufinamide         | Nuisance: somnolence, vomiting  
                    | Serious: contraindicated in familial short QT interval |
| Succinimides       | Nuisance: nausea, abdominal discomfort, anorexia, hiccups  
                    | Serious: Stevens-Johnson syndrome, drug-induced lupus |
| Tiagabine          | Nuisance: dizziness, somnolence, asthenia, headache and tremor, precipitation of absence or myoclonic seizures  
                    | Serious: precipitation of nonconvulsive status epilepticus |
| Topiramate         | Nuisance: cognitive dysfunction, weight loss, renal calculi, hypohydrosis, fever  
                    | Serious: precipitation of glaucoma |
| Valproic acid      | Nuisance: weight gain; hyperammonemia tremor, alopecia, menstrual irregularities  
                    | Serious: hepatic and pancreatic toxicity |
| Vigabatrin         | Nuisance: hyperactivity  
                    | Serious: irreversible visual field deficits, retinopathy that requires frequent ophthalmologic evaluations and follow up |
| Zonisamide         | Fatigue, dizziness, anorexia, psychomotor slowing, ataxia, rarely hallucinations, hypohydrosis and fever |

*Essentially all AEDs can cause CNS toxicity and potentially rashes and serious allergic reactions.  
AED, antiepileptic drug; CNS, central nervous system.
multiple drugs. When appropriate, levels should also be checked upon addition (or discontinuation) of a second drug because of potential drug interactions. During follow-up, repeating the EEG every few months may be helpful to evaluate changes in the predisposition to seizures. This is especially true in situations where tapering off of medication is contemplated in any seizure type and during follow-up to assess response for absence seizures, as the EEG mirrors response in such patients.

**Monitoring**

For the older AEDs, before starting treatment, baseline laboratory studies, including complete blood count, platelets, liver enzymes, and possibly kidney function tests and urinalysis, are often obtained and repeated periodically. Laboratory monitoring is more relevant early on, because idiosyncratic adverse effects such as allergic hepatitis and agranulocytosis are more likely to occur in the 1st 3-6 mo of therapy. These laboratory studies are usually initially checked once or twice during the 1st mo, then every 3-4 mo thereafter. Serious concerns have been raised about the real usefulness of routine monitoring (in the absence of clinical signs) because the yield of significant adverse effects is low and the costs may be high. There are currently many advocates of less-frequent routine monitoring.

In approximately 10% of patients, a reversible dose-related leukopenia may occur in patients on carbamazepine or on phenytoin. This adverse effect responds to decreasing the dose or to stopping the medication and should be distinguished from the much-less-common idiosyncratic aplastic anemia or agranulocytosis. One exception requiring frequent (even weekly) monitoring of liver function and of blood counts throughout the therapy is felbamate, owing to the high incidence of liver and hematologic toxicity (1 in 500 children under 2 yr of age with complex neurological disorders who are on the drug). The gum hyperplasia that is seen with phenytoin necessitates good oral hygiene (brushing teeth at least twice per day and rinsing the mouth after taking the phenytoin); in a few cases, it may be severe enough to warrant surgical reduction and/or change of medication. Allergic rash can occur with any medication, but is probably most common with lamotrigine, carbamazepine, and phenytoin.

**SIDE EFFECTS**

During follow-up the patient should be monitored for side effects. Occasionally, a Stevens-Johnson–like syndrome develops, probably most commonly with lamotrigine; it also has been found to be particularly common in Chinese patients who have the allele HLA-B*1502 and are taking carbamazepine and lamotrigine.

Another potential side effects are rickets from phenytoin, phenobarbital, primidone, and carbamazepine (enzyme inducers that reduce 25-hydroxy-vitamin D level by inducing its metabolism) and hyperammonia from valproate. Skeletal monitoring is warranted in patients on chronic AED therapy because it is often associated with vitamin D abnormalities (low bone density, rickets, and hypocalcemia) in children and adults, particularly those on enzyme-inducing medications. Thus, counseling the patient about sun exposure and vitamin D intake, monitoring its levels, and, in most cases, vitamin D supplementation are recommended. There is currently no consensus on the dose to be used for supplementation or prophylaxis, but starting doses of 400-2,000 IU/day with follow-up of the levels are reasonable.

Irreversible hepatic injury and death are particularly feared in young children (<2 yr old) who are on valproate in combination with other AEDs, particularly those who might have inborn errors of metabolism such as acidopathies and mitochondrial disease. Virtually all AEDs can produce sleepiness, ataxia, nystagmus, and slurred speech with toxic levels.

The FDA has determined that the use of AEDs may be associated with an increased risk of suicidal ideation and action and has recommended counseling about this side effect before starting these medications. This is obviously more applicable to adolescents and adults.

When adding a new AED, the doses used are often affected by the background medications. For example, if the patient is on enzyme inducers, the doses needed of valproate and lamotrigine are often double the usual maintenance doses. On the other hand, if the patient is on valproate, the doses of phenobarbital or lamotrigine are approximately half of what is usually needed. Thus, changes in the dosing of the background medication are often done as the interacting medication is being started. Genetic variability in enzymes that metabolize AEDs, and in the presence of inducible multidrug resistance genes, pharmacogenomics, might account for some of the variation among individuals in responding to certain AEDs. Although numerous variants of the cytochrome P450 enzymes have been characterized and although several multidrug resistance genes have been identified, the use of this new knowledge is currently largely restricted to research investigations, and it has yet to be applied in routine clinical practice.

**Additional Treatments**

The principles of monotherapy indicate that a second medication needs to be considered after the first either is pushed as high as tolerated and still does not control the seizures or results in intolerable adverse effects. In those cases, a second drug is started and the first is tapered and then discontinued. The second drug is then again pushed to the dose that controls the seizure or that results in intolerable side effects. If the second drug fails, monotherapy with a third drug or dual (combination) therapy is considered.

Patients with drug-resistant (previously referred to as intractable or refractory) epilepsy (those who have failed at least 2 fair trials of appropriate medications) warrant a careful diagnostic reevaluation to look for degenerative, metabolic, or inflammatory underlying disorders (e.g., mitochondrial disease, Rasmussen encephalitis; see Chapter 593.2) and to investigate them for candidacy for epilepsy surgery. Treatable metabolic disorders that can manifest as intractable epilepsy include pyridoxine-dependent and pyridoxal-responsive epilepsy; folic acid–responsive seizures (demonstrated to be the same disorder as pyridoxine-dependent epilepsy); cerebral folate deficiency; neurotransmitter disorders; biotinidase deficiency; glucose transporter 1 deficiency (responds to the ketogenic diet); serum synthesis defects; creatine deficiency syndromes; untreated phenylketonuria; developmental delay, epilepsy and neonatal diabetes; and hyperinsulinemia–hyperammonia. Often patients who do not respond to AEDs are candidates for steroids, IVIG, or the ketogenic diet.

**Steroids,** usually given as ACTH (see the discussion of West syndrome in "Severe Generalized Epilepsies" in Chapter 593.4) or as prednisone 2 mg/kg/day (or equivalent), are often used in epileptic encephalopathies such as West, Lennox-Gastaut, myoclonic atatic, continuous spike-waves in slow-wave sleep, and Landau-Kleffner syndromes. The course usually is for 2-3 mo with a taper over a similar period. Because relapses occur commonly during tapering, and in such syndromes as Landau-Kleffner and continuous spike-waves in slow-wave sleep, therapy for longer than 1 yr is often needed.

IVIG has also been reported to be similarly effective in non-immunodeficient patients with West, Lennox-Gastaut, Landau-Kleffner, and continuous spike-waves in slow-wave sleep syndromes and may also have efficacy in partial seizures. One should check the IgA levels before starting the infusions (to assess the risk for allergic reactions, because these are increased in patients with complete IgA deficiency) and guard against allergic reactions during the infusion. Low IgA, low IgG, and male sex are reported to possibly predict favorable response. The usual regimen is 2 g/kg divided over 4 consecutive days followed by 1 g/kg once a month for 6 mo. The mechanism of action of steroids and of IVIG is not known but is presumed to be antiinflammatory, because it has been demonstrated that seizures increase cytokines and that these, in turn, increase neuronal excitability by several mechanisms, including activation of glutamate receptors. Steroids and ACTH might also stimulate brain neurosteroid receptors that enhance GABA activity and might reduce corticotrophin-releasing hormone, which is known to be epileptogenic.

The ketogenic diet is believed to be effective in glucose transporter protein 1 deficiency, pyruvate dehydrogenase deficiency, myoclonic-atatic epilepsy, tuberous sclerosis complex, Rett syndrome, severe myoclonic epilepsy of infancy (Draevet syndrome), and infantile spasms. There is also suggestion of possible efficacy in selected
Part XXVII  ●  The Nervous System

mitochondrial disorders—glycogenosis type V, Landau-Kleffner syndrome, Lafora body disease, and subacute sclerosing panencephalitis. The diet is absolutely contraindicated in carnitine deficiency (primary); carnitine palmitoyltransferase I or II deficiency; carnitine translocase deficiency; β-oxidation defects; medium-chain acyl dehydrogenase deficiency; long-chain acyl dehydrogenase deficiency; short-chain acyl dehydrogenase deficiency; long-chain 3-hydroxyacyl-coenzyme A deficiency; medium-chain 3-hydroxyacyl-coenzyme A deficiency; pyruvate carboxylase deficiency; and porphyrias. Thus, an appropriate metabolic work-up, depending on the clinical picture, usually needs to be performed before starting the diet (e.g., acyl carnitine profile; total and free carnitine levels). The diet has been used for refractory seizures of various types (partial or generalized) and consists of an initial period of fasting followed by a diet with a 3:1 or 4:1 fat:nonfat ratio, with fats consisting of animal fat, vegetable oils, or medium-chain triglycerides. Many patients do not tolerate it owing to diarrhea, vomiting, hypoglycemia, dehydration, or lack of palatability. Diets such as the low-glycemic-index diet and the Atkins diet are easier to institute, do not require hospitalization, and are also useful, but it is not known yet if they are as effective as the classic diet.

**APPROACH TO EPILEPSY SURGERY**

If a patient has failed 3 drugs, the chance of achieving seizure freedom using AEDs is generally <10%. Therefore, proper evaluation for surgery is necessary as soon as patients fail 2 or 3 AEDs, usually within 2 yr of the onset of epilepsy and often sooner than 2 yr. Performing epilepsy surgery in children at an earlier stage (e.g., <5 yr of age) allows transfer of function in the developing brain. Candidacy for epilepsy surgery requires proof of resistance to AEDs used at maximum, tolerably non-toxic doses; absence of expected unacceptable adverse consequences of surgery, and a properly defined epileptogenic zone (area that needs to be resected to achieve seizure freedom). The epileptogenic zone is identified by careful analysis, by an expert team of epilepsy specialists in an epilepsy center, of the following parameters: seizure semiology, interictal EEG, video-EEG long-term monitoring, neuropsychologic profile, and MRI. Other techniques, such as invasive EEG (depth electrodes, subdural), single-photon emission CT, magnetoencephalography, and positron emission tomography are also often needed when the epileptogenic zone is difficult to localize or when it is close to eloquent cortex. To avoid resection of eloquent cortex, several techniques can be used, including the Wada test. In this test, intracarotid infusion of amobarbital is used to anesthetize 1 hemisphere to lateralize memory and speech by testing them during that unilateral anesthesia. Other tests to localize function include functional MRI, magnetoencephalography, and subdural electrodes with cortical stimulation. Developmental delay or psychiatric diseases must be considered in assessing the potential impact of surgery on the patient. The usual minimal presurgical evaluation includes EEG monitoring, imaging, and age-specific neuropsychologic assessment.

Epilepsy surgery is often used to treat refractory epilepsy of a number of etiologies, including cortical dysplasia, tuberosclerosis, polymicrogyria, hypothalamic hamartoma, Landau-Kleffner syndrome, and hemispheric syndromes, such as Sturge-Weber syndrome, hemimegalencephaly, and Rasmussen encephalitis. Patients with intractable epilepsy resulting from metabolic or degenerative problems are not candidates for resective epilepsy surgery. Focal resection of the epileptogenic zone is the most common procedure. Hemispherectomy is used for diffuse hemispheric lesions; multiple subpial transection, a surgical technique in which the horizontal connections of the epileptic focus are partially cut without resecting it, is sometimes used for unresectable foci located in eloquent cortex such as in Landau-Kleffner syndrome. In Lennox-Gastaut syndrome, corpus callosotomy is used for drop attacks. Vagal nerve stimulation is often used for intractable epilepsies of various types and for seizures of diffuse focal or multifocal anatomic origin that do not yield themselves to resective surgery. Focal resection and hemispherectomy result in a high rate (50-80%) of seizure freedom. Corpus callosotomy and vagal nerve stimulation result in lower rates (5-10%) of seizure freedom; however, these procedures do result in significant reductions in the frequency and severity of seizures, decrease in medication requirements, and meaningful improvements in the patient’s quality of life in approximately half or more of eligible patients.

**DISCONTINUATION OF THERAPY**

Discontinuation of AEDs is usually indicated when children are free of seizures for at least 2 yr. In more-severe syndromes, such as temporal lobe epilepsy secondary to mesial temporal sclerosis, Lennox-Gastaut syndrome, or severe myoclonic epilepsy, a prolonged period of seizure freedom on treatment is often warranted before AEDs are withdrawn, if withdrawal is attempted at all. In self-limited (benign) epilepsy syndromes, the duration of therapy can often be as short as 6 mo.

Many factors should be considered before discontinuing medications, including the likelihood of remaining seizure-free after drug withdrawal based on the type of epilepsy syndrome and etiology; the risk of injury in case of seizure recurrence (e.g., if the patient drives); and the adverse effects of AED therapy. Most children who have not had a seizure for 2 yr or longer and who have a normal EEG when AED withdrawal is initiated, remain free of seizures after discontinuing medication, and most relapses occur within the 1st 6 mo.

Certain risk factors can help the clinician predict the prognosis after AED withdrawal. The most important risk factor for seizure relapse is an abnormal EEG before medication is discontinued. Children who have remote structural (symptomatic) epilepsy are less likely to be able to stop AEDs than are children who have a benign genetic (idiopathic) epilepsy. In patients with absences or in patients treated with valproate for primary generalized epilepsy, the risk of relapse might still be high despite a normal EEG because valproate can normalize EEGs with generalized spike-wave abnormalities. Thus, in these patients, repeating the EEG during drug taper can help identify recurrence of the EEG abnormality and associated seizure risk before clinical seizures recur. Older age of epilepsy onset, longer duration of epilepsy, presence of multiple seizure types, and need to use more than 1 AED are all factors associated with a higher risk of seizure relapse after AED withdrawal.

AED therapy should be discontinued gradually; often over a period of 3-6 mo. Abrupt discontinuation can result in withdrawal seizures or status epilepticus. Withdrawal seizures are especially common with phenobarbital and benzo[d]azepines; consequently, special attention must be given to a prolonged tapering schedule during the withdrawal of these AEDs. Seizures that occur more than 2-3 mo after AEDs are completely discontinued indicate relapse, and resumption of treatment is usually warranted.

The decision to attempt AED withdrawal must be assessed mutually among the clinician, the parents, and the child depending on the child’s age. Risk factors should be identified and precautionary measures should be taken. The patient and family should be counseled fully on what to expect, what precautions to take (including cessation of driving for a period of time), and what to do in case of relapse. A prescription for rectal diazepam or of intranasal midazolam to be given at the time of seizures that might occur during and after tapering is usually warranted (see Table 593-12 for dosing).

**Sudden Unexpected Death in Epilepsy**

SUDEP is the most common epilepsy related mortality in patients with chronic epilepsy; the incidence is unknown but ranges from 1-5 per 1,000 people with epilepsy. Although the precise etiology is unknown, risk factors include polypharmacology, poorly controlled generalized tonic–clonic seizures, male gender, age younger than 16 yr, long duration of epilepsy, and frequent seizures. Patients are usually found dead in their bed in a prone position with evidence suggesting a recent seizure. Potential mechanisms of SUDEP include respiratory arrest or dysfunction, drug-induced cardiac toxicity, CNS dysfunction (hypoventilation, arrhythmia, suppression of brain electrical activity), or pulmonary edema. Table 593-15 lists possible preventive measures.

**Bibliography is available at Expert Consult.**
Seizures are possibly the most important and common indicator of significant neurologic dysfunction in the neonatal period. Seizure incidence is higher during this period than in any other period in life: 57.5 per 1,000 in infants with birth weights <1,500 g and 2.8 per 1,000 in infants weighing between 2,500 and 3,999 g have seizures.

**PATHOPHYSIOLOGY**

The immature brain has many differences from the mature brain that render it more excitable and more likely to develop seizures. Based predominantly on animal studies, these are delay in Na⁺, K⁺-adenosine triphosphatase maturation and increased NMDA and α-amino-3-hydroxy-5-methylisoxazole-4-propionate (AMPA) receptor density. In addition, the specific types of these receptors that are increased are those that are permeable to calcium (GLUR2 AMPA receptors). This contributes to increased excitability and to the long-term consequences associated with seizures, particularly those resulting from perinatal hypoxia. Medications that block AMPA receptors, such as topiramate, may thus prove useful in this clinical setup.

Another difference is delay in the development of inhibitory GAB-Aergic transmission. In fact, GABA in the immature brain has an excitatory function as the chloride gradient is reversed relative to the mature brain, with higher concentrations of chloride being present intracellularly than extracellularly. Thus, opening of the chloride channels in the immature brain results in depolarizing the cell and not in hyperpolarizing it. This phenomenon appears to be more prominent in male neonates, perhaps explaining their greater predisposition to seizures. The reason for this is that the Cl⁻ transporter, NKCC1, is predominantly expressed in the neonatal period, leading to transport of Cl⁻ into the cell at rest, and then to cellular depolarization upon activation of GABA_\text{A} receptors and opening of Cl⁻ channels with chloride efflux. This is important for neuronal development but renders the neonatal brain hyperexcitable. With maturation, expression of NCCK1 decreases and KCC2 increases. KCC2 transports Cl⁻ out of the cell, resulting in reduction of intracellular chloride concentration so that when GABA_\text{A} receptors are activated, Cl⁻ influx and hyperpolarization occur. Bumetanide, a diuretic that blocks NKCC1, can prevent excessive GABA depolarization and avert the neuronal hyperexcitability underlying neonatal seizures. It also prevents, in rats, complex febrile seizure hyperactivation of excitatory GABA_\text{A} receptors and the resultant granule cell ectopia and temporal lobe epilepsy.

Although it is susceptible to developing seizures, the immature brain appears to be more resistant to the deleterious effects of seizures than the mature brain, as a result of increases in calcium binding proteins that buffer injury-related increases in calcium, increased extracellular space, decreased levels of the second messenger inositol triphosphate, and the immature brain’s ability to tolerate hypoxic conditions by resorting to anaerobic energy metabolism.

Many animal studies indicate that seizures are detrimental to the immature brain. Human studies also suggest harmful effects of seizures as shown by MRI and by the association of worse prognosis in neonates with seizures even when correcting for confounding factors. Even electrographic seizures without clinical correlates have been shown to be associated with worse prognosis. However, it is not definite that this association is causal: It is difficult in human studies to distinguish among effects of seizures, of the underlying insult responsible for the seizures (clinical or electrographic), and of the AEDs used to stop the seizures. Most physicians currently believe that it is favorable to control clinical as well as electrographic seizures.

**TYPES OF NEONATAL SEIZURES**

There are 5 main neonatal seizure types: subtle, clonic, tonic, spasms, and myoclonic. Spasms, focal clonic, focal tonic, and generalized myoclonic seizures are, as a rule, associated with electrographic discharges (epileptic seizures), whereas motor automatisms, the subtle, generalized tonic and multifocal myoclonic episodes are frequently not associated with discharges and thus are thought to often represent release phenomena with abnormal movements secondary to brain injury rather than true epileptic seizures (Table 593-16). To determine clinically whether such manifestations are seizures or release phenomena is often difficult, but precipitation of such manifestations by stimulation and aborting them by restraint or manipulation would suggest that they are not seizures. One needs to keep in mind, however, that epileptic seizures can also be induced by stimulation. Thus, in many cases, specifically in sick neonates with history of neurologic insults, continuous bedside EEG monitoring helps make this distinction. Such monitoring has become the standard of care in most intensive care nurseries.

**Subtle Seizures**

Subtle seizures include transient eye deviations, nystagmus, blinking, mouthing, abnormal extremity movements (rowing, swimming, bicycling, pedaling, and stepping), fluctuations in heart rate, hypertension episodes, and apnea. Subtle seizures occur more commonly in premature than in full-term infants.

**Clonic Seizures**

Clonic seizures can be focal or multifocal. Multifocal clonic seizures incorporate several body parts and are migratory in nature. The migration follows a nonjacksonian trend; for example, jerking of the left arm can be associated with jerking of the right leg. Generalized clonic seizures that are bilateral, symmetric, and synchronous are uncommon in the neonatal period presumably due to decreased connectivity associated with incomplete myelination at this age.

**Tonic Seizures**

Tonic seizures can be focal or generalized (generalized are more common). Focal tonic seizures include persistent posturing of a limb or posturing of trunk or neck in an asymmetric way often with persistent horizontal eye deviation. Generalized tonic seizures are bilateral tonic limb extension or tonic flexion of upper extremities often associated with tonic extension of lower extremities.

**Spasms**

Spasms are sudden generalized jerks lasting 1-2 sec that are distinguished from generalized tonic spells by their shorter duration and by...

</table>

The fact that spasms are usually associated with a single, very brief, generalized discharge.

**Myoclonic Seizures**
Myoclonic seizures are divided into focal, multifocal, and generalized types. Myoclonic seizures can be distinguished from clonic seizures by the rapidity of the jerks (<50 msec) and by their lack of rhythmicity. Focal myoclonic seizures characteristically affect the flexor muscles of the upper extremities and are sometimes associated with seizure activity on EEG. Multifocal myoclonic movements involve asynchronous twitching of several parts of the body and are not commonly associated with seizure discharges on EEG. Generalized myoclonic seizures involve bilateral jerking associated with flexion of upper and occasionally lower extremities. The latter type of myoclonic jerks is more commonly correlated with EEG abnormalities than the other types.

**Seizures vs Jitteriness**
Jitteriness can be defined as rapid motor activities, such as a tremor or shake, that can be ended by flexion or holding the limb. Seizures, on the other hand, generally do not end with tactile or motor suppression. Jitteriness, unlike most seizures, is usually induced by a stimulus. Also unlike jitteriness, seizures often involve eye deviation and autonomic changes.

**ETIOLOGY**
Table 593-17 lists causes of neonatal seizures.

**Hypoxic–Ischemic Encephalopathy**
This is the most common cause of neonatal seizures, accounting for 50-60% of patients. Seizures secondary to this encephalopathy occur within 12 hr of birth.

**Vascular Events**
These include intracranial bleeds and ischemic strokes and account for 10-20% of patients. Three types of hemorrhage can be distinguished: primary subarachnoid hemorrhage, germinal matrix–intraventricular hemorrhage, and subdural hemorrhage. Patients with arterial strokes or venous sinus thrombosis can present with seizure and these can be

Tuberous sclerosis
Sturge-Weber syndrome

Diagnosed by neuroimaging. Venous sinus thrombosis could be missed unless MR or CT venography studies are requested.

Intracranial Infections
Bacterial and nonbacterial infections account for 5-10% of the cases of neonatal seizures and include bacterial meningitis, TORCH (toxoplasmosis, other infections, rubella, cytomegalovirus, herpes simplex virus) infections, particularly herpes simplex encephalitis.

Brain Malformations
Brain malformations account for 5-10% of neonatal seizure cases. An example is Aicardi syndrome, which affects girls only and consists of retinal lacunae, agenesis of the corpus callosum, and severe seizures including subsequent infantile spasms with hypertonia that is sometimes initially unilateral on EEG.

Metabolic Disturbances
Metabolic disturbances include disturbances in glucose, calcium, magnesium, other electrolytes, amino acids, or organic acids and pyridoxine dependency.

Hypoglycemia can cause neurologic disturbances and is very common in small neonates and neonates whose mothers are diabetic or prediabetic. The duration of hypoglycemia is very critical in determining the incidence of neurologic symptoms.

Hypocalcemia occurs at 2 peaks. The first peak corresponds to low-birthweight infants and is evident in the 1st 2-3 days of life. The second peak occurs later in neonatal life and often involves large, full-term babies who consume milk that has an unfavorable ratio of phosphorus to calcium and phosphorus to magnesium. Hypomagnesemia is often associated with hypocalcemia. Hyponatremia can cause seizures and is often secondary to inappropriate antidiuretic hormone secretion.

Local anesthetic intoxication seizures can result from neonatal intoxication with local anesthetics administered into the infant’s scalp.

Neonatal seizures can also result from disturbances in amino acid or organic acid metabolism. These are usually associated with acidosis and/or hyperammonemia. However, even in the absence of these findings, if a cause of the seizures is not immediately evident, then ruling out metabolic causes requires a full metabolic work-up (see Chapter 593.2) including examination of serum amino acids, acyl carnitine profile, lactate, pyruvate, ammonia, very-long-chain fatty acids (for neonatal adrenoleukodystrophy and Zellweger syndrome), examination of urine for organic acids, α-aminoadipic acid semialdehyde and sulfoxo cysteine, as well as examination of CSF for glucose, protein, cells, amino acids, lactate, pyruvate, α-aminoadipic acid semialdehyde, pyridoxal phosphate, 5-MTHF (5-methyltetrahydrofolate), succinyladenosine, and CSF neurotransmitter metabolites. This is because many inborn errors of metabolism, such as nonketotic hyperglycinemia, can manifest with neonatal seizures (often mistaken initially for hiccups that these patients also have) and can be detected only by performing these tests. Definitive diagnosis of nonketotic hyperglycinemia, for example, requires measuring the ratio of CSF glycine to plasma glycine.

Pyridoxine and pyridoxal dependency disorders can cause severe seizures. These seizures, which are often multifocal clonic, usually start during the 1st few hr of life. Cognitive impairment is often associated if therapy is delayed (see Chapter 593.6).

Drug Withdrawal
Seizures can rarely be caused by the neonate’s passive addiction and then drug withdrawal. Such drugs include narcotic analgesics, sedative-hypnotics, and others. The associated seizures appear during the 1st 3 days of life.

Neonatal Seizure Syndromes
Seizure syndromes include benign idiopathic neonatal seizures (fifth day fits), which are usually apneic and focal motor seizures that start around the fifth day of life. Interictal EEG shows a distinctive pattern called theta pointu alternant (runs of sharp 4-7 Hz activity), and ictal EEG shows multifocal electrographic seizures. Patients have a good response to medications and a good prognosis. Autosomal dominant benign familial neonatal seizures have onset at 2-4 days of age and usually remit at 2-15 wk of age. The seizures consist of ocular deviation, tonic posturing, clonic jerks, and, at times, motor automatisms. Interictal EEG is usually normal. These are caused by mutations in the KCNQ2 and KCNQ3 genes. Approximately 16% of patients develop later epilepsy. Early myoclonic encephalopathy and early infantile epileptic encephalopathy (Ohtahara syndrome) are discussed in Chapter 593.4.
Miscellaneous Conditions

Miscellaneous conditions include benign neonatal sleep myoclonus and hyperekplexia, which are nonepileptic conditions (see Chapter 594).

DIAGNOSIS

Some cases can be correctly diagnosed by simply taking the prenatal and postnatal history and performing an adequate physical examination. Depending on the case, additional tests or procedures can be performed. EEG is considered the main tool for diagnosis. It can show paroxysmal activity (e.g., sharp waves) in between the seizures and electrographic seizure activity if a seizure is captured. However, some neonatal seizures might not be associated with EEG abnormalities as noted above either because they are “release phenomena” or alternatively because the discharge is deep and is not detected by the scalp EEG. Additionally, electrographic seizures can occur without observed clinical signs (electroclinical dissociation). This is presumed to be caused by the immaturity of cortical connections, resulting, in many cases, in no or minimal motor manifestations. Continuously monitoring the EEG at the bedside in the neonatal intensive care unit for neonates at risk for neonatal seizures and brain injury is part of routine clinical practice in most centers, providing real-time measurements of the brain’s electrical activity and identifying seizure activity. Many centers apply EEG monitoring to at-risk babies even before seizures develop, which is often desirable; others monitor patients who have manifested or are suspected of having seizures. In addition, there are currently attempts to develop methods for continuous monitoring of cerebral activity with automated detection and background analysis of neonatal seizures, similar to the continuous ECG monitoring in intensive care facilities. In infants started on hypothermia protocols following suspected hypoxic–ischemic injuries, it is recommended to continuously monitor the EEG during the cooling and rewarming periods to detect clinical and subclinical events in this high-risk population. The American Clinical Neurophysiology Society recommends continuous EEG monitoring in the neonatal intensive care unit to monitor evolution of EEG background to help with prognostication, to guide treatment of anticonvulsant therapy for infants with established seizures, to screen for seizures among infants deemed to be at risk (hypoxic ischemic encephalopathy, stroke, meningitis, intraventricular hemorrhage, metabolic disorders, and congenital cerebral malformations), to screen for seizures among infants who are paralyzed, to characterize clinical events suspected to represent seizures, and to detect impending cerebral ischemia or hemorrhage.

Careful neurologic examination of the infant might uncover the cause of the seizure disorder. Examination of the retina might show the presence of chorionretinitis, suggesting a congenital TORCH infection, in which case titers of mother and infant are indicated. The Aicardi syndrome is associated with coloboma of the iris and retinal lacunae. Inspection of the skin might show hypopigmented lesions characteristic of tuberous sclerosis (seen best on UV light examination) or the typical crusted vesicular lesions of incontinentia pigmenti; both neurocutaneous syndromes are often associated with generalized myoclonic seizures beginning early in life. An unusual body or urine odor suggests an inborn error of metabolism.

Blood should be obtained for determinations of glucose, calcium, magnesium, electrolytes, and blood urea nitrogen. If hypoglycemia is a possibility, serum glucose testing is indicated so that treatment can be initiated immediately. Hypocalcemia can occur in isolation or in association with hypomagnesemia. A lowered serum calcium level is often associated with birth trauma or a CNS insult in the perinatal period. Additional causes include maternal diabetes, prematurity, DiGeorge syndrome, and high-phosphate feedings. Hypomagnesemia (<1.5 mg/dL) is often associated with hypocalcemia and occurs particularly in infants of malnourished mothers. In this situation, the seizures are resistant to calcium therapy but respond to intramuscular magnesium, 0.2 mL/kg of a 50% solution of MgSO4. Serum electrolyte measurement can indicate significant hyponatremia (serum sodium <115 mEq/L) or hypernatremia (serum sodium >160 mEq/L) as a cause of the seizure disorder.

A lumbar puncture is indicated in virtually all neonates with seizures, unless the cause is obviously related to a metabolic disorder such as hypoglycemia or hypocalcemia. The latter infants are normally alert interictally and usually respond promptly to appropriate therapy. The CSF findings can indicate a bacterial meningitis or aseptic encephalitis. Prompt diagnosis and appropriate therapy improve the outcome for these infants. Bloody CSF indicates a traumatic tap or a subarachnoid or intraventricular bleed. Immediate centrifugation of the specimen can assist in differentiating the 2 disorders. A clear supernatant suggests a traumatic tap, and a xanthochromic color suggests a subarachnoid bleed. Mildly jaundiced normal infants can have a yellowish discoloration of the CSF that makes inspection of the supernatant less reliable in the newborn period.

Many inborn errors of metabolism cause generalized convulsions in the newborn period. Because these conditions are often inherited in an autosomal recessive or X-linked recessive fashion, it is imperative that a careful family history be obtained to determine if there is consanguinity or whether siblings or close relatives developed seizures or died at an early age. Serum ammonia determination is useful for screening for the hypoglycemic hyperammonemia syndrome and for suspected urea cycle abnormalities. In addition to having generalized clonic seizures, these latter infants present during the 1st few days of life with increasing lethargy progressing to coma, anorexia and vomiting, and a bulging fontanel. If the blood gases show an anion gap and a metabolic acidosis with the hyperammonemia, urine organic acids should be immediately determined to investigate the possibility of methylmalonic or propionic acidemia.

Maple syrup urine disease should be suspected when a metabolic acidosis occurs in association with generalized clonic seizures, vomiting, bulging fontanel, and muscle rigidity during the 1st wk of life. The result of a rapid screening test using 2,4-dinitrophenylhydrazine that identifies keto derivatives in the urine is positive in maple syrup urine disease.

Additional metabolic causes of neonatal seizures include nonketotic hyperglycinemia, an intractable condition characterized by markedly elevated plasma and CSF glycine levels, prominent hiccupps, persistent generalized seizures, and lethargy rapidly leading to coma; ketotic hyperglycinemia in which seizures are associated with vomiting, fluid and electrolyte disturbances, and a metabolic acidosis; and Leigh disease suggested by elevated levels of serum and CSF lactate or an increased lactate:pyruvate ratio. Biotinidase deficiency should also be considered. A comprehensive description of the diagnosis and management of these metabolic diseases is discussed in Part XI, Metabolic Disorders.

Unintentional injection of a local anesthetic into a fetus during labor can produce intense tonic seizures. These infants are often thought to have had a traumatic delivery because they are flaccid at birth, have abnormal brainstem reflexes, and show signs of respiratory depression that sometimes require ventilation. Examination may show a needle puncture of the skin or a perforation or laceration of the scalp. An elevated serum anesthetic level confirms the diagnosis. The treatment consists of supportive measures and promotion of urine output by administering intravenous fluids with appropriate monitoring to prevent fluid overload.

Benign familial neonatal seizures, an autosomal dominant condition, begins on the 2nd-3rd day of life, with a seizure frequency of 10-20/day. Patients are normal between seizures, which stop in 1-6 mo. These are caused by mutations in the voltage-sensitive potassium channel genes Kv7.2, and Kv7.3 (KCNQ2 and KCNQ3). Other mutations in the Kv7.2 gene cause severe neonatal epileptic encephalopathy. Fifth-day fits occur on day 5 of life (4-6 days) in normal-appearing neonates. The seizures are multifocal and are often present for <24 hr. The diagnosis requires exclusion of other causes of seizures and sequencing of the above genes. The prognosis is good for the benign form.

Pyridoxine dependency, a rare disorder, must be considered when seizures begin shortly after birth with signs of fetal distress in utero and are resistant to conventional anticonvulsants such as phenobarbital or phenytoin. The history may suggest that similar seizures
occurred in utero. When pyridoxine-dependent seizures are suspected, 100–200 mg of pyridoxine or pyridoxal phosphate should be administered intravenously during the EEG, which should be promptly performed once the diagnosis is considered. The seizures abruptly cease, and the EEG often normalizes in the next few hours or longer. Not all cases of pyridoxine dependency respond dramatically to the initial bolus of IV pyridoxine. Therefore, a 6-wk trial of oral pyridoxine (100–200 mg/day) or preferably pyridoxal phosphate (as pyridoxine does not help infants with the related but distinct syndrome of pyridoxal dependency) is recommended for infants in whom a high index of suspicion continues after a negative response to IV pyridoxine. Measurement of serum pipercolic acid and α-aminoadipic acid semialdehyde (elevated) and CSF pyridoxal-5-phosphate (decreased) needs to be performed before initiation of the trials without delay. These children require lifelong supplementation of oral pyridoxine (100 mg/day at times with folinic acid) or pyridoxal phosphate (15-60 mg/kg/day). Cerebral folate deficiency should also be ruled out by medication trial (folinic acid 1-3 mg/kg/day) and by CSF levels of 5-methyltetrahydrofolate assay. Gene sequencing can confirm the diagnosis (see Chapter 593.4). The earlier the therapy is initiated in these vitamin responsive disorders, the more favorable the outcome.

Drug-withdrawal seizures can occur in the newborn nursery but can take several weeks to develop because of prolonged excretion of the drug by the neonate. The incriminated drugs include barbiturates, benzodiazepines, heroin, and methadone. The infant may be jittery, irritable, and lethargic, and can have myoclonus or frank clonic seizures. The mother might deny the use of drugs; a serum or urine drug screen might identify the responsible agent.

Infants with focal seizures, suspected stroke or intracranial hemorrhage, and severe cytoarchitectural abnormalities of the brain (including lissencephaly and schizencephaly) who clinically may appear normal or microcephalic should undergo MRI or CT scan. Indeed, it is appropriate to recommend imaging of all neonates with seizures unexplained by serum glucose, calcium, or electrolyte disorders. Infants with chromosome abnormalities and adrenoleukodystrophy are also at risk for seizures and should be evaluated with investigation of a karyotype and serum very-long-chain fatty acids, respectively.

**PROGNOSIS**

Over the last few decades, prognosis of neonatal seizures has improved owing to advancements in obstetric and intensive neonatal care. Mortality has decreased from 40% to 20%. The correlation between EEG and prognosis is very clear. Although neonatal EEG interpretation is very difficult, EEG was found to be highly associated with the outcome in premature and full-term infants. An abnormal background is a powerful predictor of less-favorable later outcome. In addition, prolonged electrographic seizures (>10 min/hr), multifocal periodic electrographic discharges, and spread of the electrographic seizures to the contralateral hemisphere also correlate with poorer outcome. The underlying etiology of the seizures is the main determinant of outcome. For example, patients with seizures secondary to hypoxic–ischemic encephalopathy have a 50% chance of developing normally, whereas those with seizures caused by primary subarachnoid hemorrhage or hypocalcemia have a much better prognosis.

**TREATMENT**

A mainstay in the therapy of neonatal seizures is the diagnosis and treatment of the underlying etiology (e.g., hypoglycemia, hypocalcemia, meningitis, drug withdrawal, trauma), whenever one can be identified. There are conflicting approaches regarding the control of neonatal seizures. Most experts advocate complete control of clinical as well electrographic seizures. Others argue for treating clinical seizures only. Most centers favor the first approach. An important consideration before starting anticonvulsants is deciding, based on the severity duration and frequency of the seizures if the patient needs to receive intravenous therapy and loading with an initial bolus or can simply be started on maintenance doses of a long-acting drug. Patients often require assisted ventilation after receiving intravenous or oral loading doses of AEDs, and thus precautions for observations and for needed interventions are necessary.

**Lorazepam**

The initial drug used to control acute seizures is usually lorazepam. Lorazepam is distributed to the brain very quickly and exerts its anticonvulsant effect in <5 min. It is not very lipophilic and does not clear out from the brain very rapidly. Its action can last 6-24 hr. Usually, it does not cause hypotension or respiratory depression. The dose is 0.05 mg/kg (range: 0.02-0.10 mg/kg) every 4-8 hr.

**Diazepam**

Diazepam can be used as an alternative initial drug. It is highly lipophilic, so it distributes very rapidly into the brain and then is cleared very quickly out, carrying the risk of recurrence of seizures. Like other intravenous benzodiazepines, it carries a risk of apnea and hypotension, particularly if the patient is also on a barbiturate, so patients need to be observed for 3-8 hr after administration. The usual dose is 0.1-0.3 mg/kg IV over 3-5 min, given every 15-30 min to a maximum total dose of 2 mg. However, because of the respiratory and blood pressure limitations and because the intravenous preparation contains sodium benzoate and benzoic acid, it is currently not recommended as a first-line agent.

**Midazolam**

Midazolam can be used as an initial drug as a bolus or as a second- or third-line drug as a continuous drip for patients who did not respond to phenobarbital and/or to phenytoin. The doses used have been in the range of 0.05–0.1 mg/kg IV initial bolus, with a continuous infusion of 0.5-1 µg/kg/min IV that can then be gradually titrated upward, if tolerated, every 5 min or longer, to a maximum of approximately 33 µg/kg/min (2 mg/kg/hr).

**Phenobarbital**

Phenobarbital is considered by many as the first choice long-acting drug in neonatal seizures. Whether to use a benzodiazepine first depends on the clinical situation. The usual loading dose is 20 mg/kg. If this dosage is not effective, then additional doses of 5-10 mg/kg can be given until a dose of 40 mg/kg is reached. Respiratory support may be needed after phenobarbital loading. Twenty-four hours after starting the loading dose, maintenance dosing can be started at 3-6 mg/kg/day usually administered in 2 separate doses. Phenobarbital is metabolized in the liver and is excreted through kidneys. Thus, any abnormality in the function of these organs alters the drug's metabolism and can result in toxicity. In infants with acidosis or critical illness that might alter serum protein content, free (i.e., not protein bound) levels of the drug should be followed carefully.

**Phenytoin and Fosphenytoin**

For ongoing seizures, if a total loading dose of 40 mg/kg of phenobarbital was not effective, then a loading dose of 15-20 mg/kg of phenytoin can be administered intravenously. The rate at which the dose should be given must not exceed 0.5-1.0 mg/kg/min so as to prevent cardiac problems, and the medication needs to be avoided in patients with significant heart disease. Heart rate should be monitored while administering the drug. It is not possible to mix phenytoin or fosphenytoin with dextrose solutions. Owing to its reduced solubility, potentially severe local cutaneous reactions, interaction with other drugs, and possible cardiac toxicity, intravenous phenytoin is not widely used.

Fosphenytoin, which is a phosphate ester prodrug, is preferable. It is highly soluble in water, and can be administered very safely intravenously and intramuscularly, without causing injury to tissues. Fosphenytoin is administered in phenytoin equivalents (PE). The usual loading dose of fosphenytoin is 15-20 PE/kg administered over 30 min. Maintenance doses of 4-8 PE/kg/day can be given. As is the case for phenobarbital, free levels of the drug should be monitored in neonates whose serum pH or protein content might not be normal.
**Other Medications**

Approximately 45% of neonates respond to the first drug used if it is phenobarbital or phenytoin and an additional 15% respond to the second agent. Levetiracetam (which can be given intravenously with later convenient conversion to oral solution) and topiramate (oral) are reported to be the drugs of second and third choice for approximately half of surveyed pediatric neurologists and some have used them even before phenobarbital or phenytoin in selected cases. The dosages used are 10-30 mg/kg/day of levetiracetam, at times higher, and up to 20 mg/kg/day of topiramate. Bumetanide has been used as an adjunct drug, particularly with phenobarbital, because of its effect on the chloride gradient, as discussed above. Lidocaine is another medication used for resistant cases. Primidone, carbamazepine, valproate, and lamotrigine use, although reported in some studies, is rarely warranted. Valproate, for example, is more likely to be toxic in children younger than 2 yr of age than in older children.

**Duration of Therapy**

Duration of therapy is related to the risk of developing later epilepsy in infants suffering from neonatal seizures, which ranges from 10-30% and depends on the individual neurologic examination, the etiology of the seizures, and the EEG at the time of discharge from the hospital. In general, if the EEG at the time of discharge does not show evidence of epileptiform activity, then medications are usually tapered at that time. If the EEG remains paroxysmal, then the decision is usually delayed for several months after discharge.

**593.8 Status Epilepticus**

_Mohamad A. Mikati and Abeer J. Hani_

_Status epilepticus_ is a medical emergency that should be anticipated in any patient who presents with an acute seizure. It is defined as continuous seizure activity or recurrent seizure activity without regaining of consciousness lasting for more than 5 min as part of an operational definition put forth within the past few years. In the past, the cutoff time was 30 min, but this has been reduced to emphasize the risks involved with the longer durations. The ILAE defines status epilepticus as “a seizure which shows no clinical signs of arresting after a duration encompassing the great majority of seizures of that type in most patients or recurrent seizures without resumption of baseline central nervous system function interictally.” The measures used to treat status epilepticus have to be started in any patient with acute seizures that do not stop within a few minutes. The most common type is _convulsive status epilepticus_ (generalized tonic, clonic, or tonic–clonic), but other types do occur, including _nonconvulsive status_ (complex partial, absence), myoclonic status, epilepsy partialis continua, and neonatal status epilepticus. The incidence of status epilepticus ranges between 10 and 60 per 100,000 population in various studies. Status epilepticus is most common in children younger than 5 yr of age, with an incidence in this age group of >100 per 100,000 children.

Approximately 30% of patients presenting with status epilepticus are having their first seizure, and approximately 40% of these later develop epilepsy. Febrile status epilepticus is the most common type of status epilepticus in children. In the 1950s and 1960s, mortality rates of 6-18% were reported after status epilepticus; currently, with the recognition of status epilepticus as a medical emergency, a lower mortality rate of 4-5% is observed, most of it secondary to the underlying etiology rather than to the seizures. Status epilepticus carries an approximately 14% risk of new neurologic deficits, most of this (12.5%) secondary to the underlying pathology.

_Nonconvulsive status epilepticus_ manifests as a confusional state, dementia, hyperactivity with behavioral problems, fluctuating impairment of consciousness with at times unsteady sitting or walking, fluctuating mental status, confusional state, hallucinations, paranoia, aggressiveness catatonia, and or psychotic symptoms. It should be considered in any of these situations, especially in an unresponsive or encephalopathic child. Epilepsia partialis continua has been defined previously and can be caused by tumor, vascular etiologies, mitochondrial disease (mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke-like episodes [MELAS]), and Rasmussen encephalitis.

_Refractory status epilepticus_ is status epilepticus that has failed to respond to therapy, usually with at least 2 (such as a benzodiazepine and another medication) medications. Currently, the trend is not to assign a minimum duration, whereas in the past a minimum duration of 30 min, 60 min, or even 2 hr was cited. _New-onset refractory status epilepticus_ has been identified as a distinct entity that can be caused by almost any of the causes of status epilepticus in a patient without prior epilepsy. It also is often of unknown etiology, presumed to be encephalitic or postencephalitic, can last several weeks or longer, and often, but not always, has a poor prognosis. Devastating epileptic encephalopathy in school-age children, also called _fever-induced refractory epileptic encephalopathy in school age children_ (FIRES) is a syndrome of refractory status epilepticus that is associated with acute febrile infections, appears to be parainfectious in nature, and to be highly drug resistant but responsive to the ketogenic diet.

**ETIOLOGY**

Etiologies include new-onset epilepsy of any type; drug intoxication (e.g., tricyclic antidepressants) in children and drug and alcohol abuse in adolescents; drug withdrawal or overdose in patients on AEDs; hypoglycemia; hypocalcemia; hyponatremia; hypomagnesemia; acute head trauma; encephalitis; meningitis; autoimmune encephalitis (such as anti-NMDA receptor and anti–voltage-gated potassium channel complex antibody syndromes); ischemic (arterial or venous) stroke; intracranial hemorrhage; folinic acid and pyridoxine and pyridoxal phosphate dependency (these usually present in infancy but childhood onset is also possible); inborn errors of metabolism (see _Chapter 593.2_) such as nonketotic hyperglycinemia in neonates and mitochondrial encephalopathy with lactic acidosis (MELAS) in infants, children, and adolescents; ion channel–related epilepsies (e.g., sodium and potassium channel mutations reviewed in the sections above); hypoxic–ischemic injury (e.g., after cardiac arrest); systemic conditions (such as hypertensive encephalopathy, posterior reversible encephalopathy, renal or hepatic encephalopathy); brain tumors; and any other disorders that can cause epilepsy (such as brain malformations, neurodegenerative disorders, different types of progressive myoclonic epilepsy, storage diseases).

A rare condition called _hemiconvulsion-hemiplegia-epilepsy syndrome_ consists of prolonged febrile status epilepticus presumably caused by focal acute encephalitis with resultant atrophy in the involved hemisphere, contralateral hemiplegia, and chronic epilepsy. It should be suspected early on to attempt to control the seizures as early as possible. This and the somewhat similar condition mentioned above called FIRES are likely to be have a parainfectious-autoimmune etiology. Rasmussen encephalitis often causes epilepsia partialis continua (see _Chapter 593.3_) and sometimes convulsive status epilepticus. Several types of infections are more likely to cause encephalitis with status epilepticus, such as herpes simplex (complex partial and convulsive status), _Bartonella_ (particularly nonconvulsive status), _Epstein-Barr virus_, and mycoplasma (postinfectious encephalomyelitis with any type of status epilepticus). Postinfectious encephalitis and acute disseminated encephalomyelitis are common causes of status epilepticus, including refractory status epilepticus. HHV6 can cause a distinct epileptic syndrome with limbic status epilepticus in immune-suppressed patients.

**MECHANISMS**

The mechanisms leading to the establishment of sustained seizure activity seen in status epilepticus appear to involve (1) failure of desensitization of AMPA glutamate receptors, thus persistence of increased excitability, and (2) reduction of GABA-mediated inhibition as a result of intracellular internalization of GABA<sub>A</sub> receptors. This explains the
Bibliography

Clinical observation that status epilepticus is often less likely to stop in the next specific period of time than the longer the seizure has lasted and why benzodiazepines appear to be decreasingly effective the longer seizure activity lasts. During status epilepticus there is increased cerebral metabolic rate and a compensatory increase in cerebral blood flow that, after approximately 30 min, is not able to keep up with the increases in cerebral metabolic rate. This leads to a transition from adequate to inadequate cerebral oxygen tensions and, together with other factors, contributes to neuronal injury resulting from status epilepticus. Status epilepticus can cause both neuronal necrosis and apoptosis. The mechanisms of apoptosis are thought to be related to increases in intracellular calcium and proapoptotic factors such as ceramide, Bax, and apoptosis-inducing factor. In addition, inflammation through the cytokines (such as interleukin-1β) released during seizure activity can modify neuronal excitability by modifying neurotransmitter function in a number of ways, such as through phosphorylation of the NR2B subunit rendering the NMDA receptors more permeable to calcium influx, increased expression of highly calcium-permeable AMPA receptors, and induction of endocytosis of GABA<sub>A</sub> receptors. Prostaglandins (such as prostaglandin E<sub>2</sub>) can increase glutamate release and reduce potassium currents leading to increased excitability.

**Therapy**

Status epilepticus is a medical emergency that requires initial and continuous attention to securing airway, breathing, and circulation (with continuous monitoring of vital signs including ECG) and determination and management of the underlying etiology (e.g., hypoglycemia). Laboratory studies, including glucose, sodium, calcium, magnesium, complete blood count, basic metabolic panel, CT scan, and continuous EEG, are needed for all patients. Blood and spinal fluid cultures, toxic screens, and tests for inborn errors of metabolism are often needed. AED levels need to be determined in all patients known already to be taking these drugs. Lumbar puncture, comprehensive toxicologic screens, MRI, and other laboratory tests are performed depending on clinical suspicion and need. EEG is helpful in ruling out pseudo-status epilepticus (psychologic reaction mimicking status epilepticus) or other movement disorders (chorea, tics), rigors, clonus with stimulation, and decerebrate/decorticate posturing. The EEG can also be helpful in identifying the type of status epilepticus (generalized vs focal), which can guide further testing for the underlying etiology and further therapy. EEG can also help distinguish between postictal depression and later stages of status epilepticus in which the clinical manifestations are subtle (e.g., minimal myoclonic jerks) or absent (electroclinical dissociation), and can help in monitoring the therapy, particularly in patients who are paralyzed and intubated. Neuroimaging must be considered after the child has been stabilized, especially if it is indicated by the clinical manifestations, by an asymmetric or focal nature of the EEG abnormalities, or by lack of knowledge of the underlying etiology. The EEG manifestations of status epilepticus show several stages that consist of initial distinct electrographic seizures (stage I) followed by waxing and waning electrographic seizures (stage II), continuous electrographic seizures (stage III; many patients start with this directly), continuous ictal discharges punctuated by flat periods (stage IV), and periodic epileptiform discharges on flat background (stage V). The last 2 stages are often associated with subtle clinical manifestations and with a lower chance of response to medications.

The initial emergent therapy usually involves intravenous diazepam, lorazepam, or midazolam. Diazepam is at least as effective as intravenous lorazepam but has fewer side effects (Table 593-18). The use of midazolam autoinjector as initial therapy for acute seizures was found to be at least as useful and safe as the use intravenous lorazepam and results in earlier response. If intravenous access is not available, buccal or intranasal midazolam, intranasal lorazepam, or rectal diazepam are effective options. Intramuscular midazolam is equally effective as intravenous lorazepam. With all options, respiratory depression is a potential side effect for which the patient should be monitored and managed as needed. In some infants, a trial of pyridoxine may be warranted. The strongest evidence for initial and emergent therapy is for diazepam or

PE, phenytoin sodium equivalents.
achievement of complete flattening of the EEG. Some consider that method of choice by which to follow them. The goal is to stop electro-
depending on clinical and EEG responses. Because most of these pentobarbital, or thiopental is used. This is done in the ICU. Subsequent
bolus with higher infusion rates (1 PE/kg for fosphenytoin) increases the
serum concentration by approximately 1 µg/mL; for valproate, each 1 mg/kg increases the serum concentration by approximately 4 µg/mL. Precautions about the rate of infusion of fosphenytoin and phenytoin (not >0.5-1.0 mg/kg/ min) and the other medications need to be followed because side effects often depend on infusion rate. The subsequent medication is often phenobarbital. The dose used in neonates is usually 20 mg/kg loading dose, but in infants and children the dose is often 5-10 mg/kg (to avoid respiratory depression), with the dose repeated if there is not an adequate response. Current evidence for the urgent therapy is strongest for valproate, followed by phenytoin/fosphenytoin and midazolam continuous infusion, followed by phenobarbital and levetiracetam, the last of which are currently being increasingly used.

After the second or third medication is given, and sometimes before that, the patient might need to be intubated. All patients with status epilepticus, even the ones who respond, need to be admitted to the ICU for completion of therapy and monitoring. Ideally, emergent and urgent therapies should have been received within less than 30 min so as to initiate the subsequent therapy soon, thus reducing the chances of sequelae. For refractory status epilepticus treatment, an intravenous bolus followed by continuous infusion of midazolam, propofol, pentobarbital, or thiopental is used. This is done in the ICU. Subsequent boluses and adjustment of the rate of the infusion are usually made depending on clinical and EEG responses. Because most of these patients need to be intubated and paralyzed, the EEG becomes the method of choice by which to follow them. The goal is to stop electrographic seizure activity before reducing the therapy. Usually this implies achievement of complete flattening of the EEG. Some consider that achieving a burst suppression pattern may be enough, and the periods of flattening in such a case need to be 8-20 sec to ensure interruption of electrographic seizure activity. However, this is an area that is in need of further study. Currently, the level of the evidence for refractory treatment is strongest for midazolam and valproate, followed by propofol and pentobarbital/thiopental, followed by levetiracetam, phenytoin/fosphenytoin, lacosamide, topiramate, and phenobarbital.

Patients on these therapies require careful attention to blood pressure and to systemic complications, and some develop multiorgan failure. It is not unusual for patients put into pentobarbital coma to have to be on multiple pressors to maintain their blood pressure during therapy.

The choice among the above options to treat refractory status epilepticus often depends on the experience of the specific center. Midazolam probably has fewer side effects, but is less effective, and barbiturate coma is more effective, but carries a higher risk of side effects. For refractory status epilepticus, even months. Even though the prognosis in new-onset refractory status epilepticus (new-onset refractory status epilepticus), such therapies need to be maintained for several weeks or even months. Although no known “reflex” may be involved, more appropriate terms may be sensory precipitated or stimulus sensitive seizures (see Table 593-1). Stimuli may be external (light, patterns, music, brushing teeth) or internal (math, reading, thinking, self-induced). Reflex seizures may be generalized, partial, nonconvulsive, absence or myoclonic. One common pattern is photomycoclonic seizures characterized by forehead muscle twitching or repetitive eye opening or closing.

Many patients with epilepsy can identify precipitating or provoking events that predispose them to having a seizure. Common events in patients with epilepsy include stress, lack of sleep, fever, or fatigue.

There is another group of patients who have seizures in response to a very specific, identifiable sensory stimulus or activity and are considered to have reflex seizures. Although no known “reflex” may be involved, more appropriate terms may be sensory precipitated or stimulus sensitive seizures (see Table 593-1). Stimuli may be external (light, patterns, music, brushing teeth) or internal (math, reading, thinking, self-induced). Reflex seizures may be generalized, partial, nonconvulsive, absence or myoclonic. One common pattern is photomycoclonic seizures characterized by forehead muscle twitching or repetitive eye opening or closing.

Photomycoclonic seizures are a well-recognized disorder stimulated by bright or flashing lights (TV, video games, discotheques, concert light shows) or by patterns (TV, video games, lines on the road while traveling). Visual sensitivity may occur in 0.3-3% of the population, while photosensitive or pattern-induced seizures may occur in 1 in 4,000 people in the at-risk age group of 5-25 yr. When Japanese children were exposed to a Pokémon cartoon that induced seizures, only 24% had a history of spontaneous seizures. Patients tend to outgrow photosensitive or pattern-induced seizures in their 30s. Photoparoxysmal responses, with an abnormal EEG response to photic stimulation may be more common than photic-induced seizures. There are some photo-induced responses that do not demonstrate EEG abnormalities (nonconvulsive).

For patients with isolated photosensitive or pattern-induced seizures, avoidance or modification of stimuli is the initial approach. Such activities may include blue or polarized sunglasses, avoiding high-contrast flashing-light video games, avoiding discotheques, use a TV remote or watch TV in a well-lit room at a distance of >8 feet, and covering 1 eye when in a provocative situation.
Bibliography

Bibliography

Nodding syndrome appears to be an epidemic progressive epilepsy encephalopathy syndrome of unknown etiology seen predominantly in Uganda, Liberia, Tanzania, and the southern Sudan, with a prevalence of approximately 6.8 per 1,000 children. Age of onset is 6-13 yr.

Nodding episodes are characterized by at least daily, rapid, paroxysmal forward head bobbling spells lasting several minutes; some patients are unresponsive whereas others may respond to commands or continue what they were doing before the episode. Children were previously healthy, although there may be a family history of seizures. In addition to episodes of nodding, there may be associated definable generalized tonic–clonic or absence seizures. Furthermore, patients go on to demonstrate severe and global cognitive impairment (see Table 593-19 for case definitions).

The EEG demonstrates a disorganized slow background and interictal generalized 2.5-3.0 Hz spike and slow waves. During a nodding episode, the EEG demonstrates generalized electrodecrement and paraspinal electromyography dropout suggestive of an atonic seizure. Cerebral spinal fluid analysis is usually negative, while the MRI shows cerebral and cerebellar atrophy.

Nodding episodes may be triggered during meals while eating hot foods or drinking cold liquids; cold environmental temperature may also trigger a nodding episode.

Treatment of seizures are indicated; however, the response to treatment is poor.

Bibliography is available at Expert Consult.

Bibliography

The misdiagnosis of epilepsy is estimated to be as high as 5-40%, implying that many patients may be subjected to unnecessary therapy and tests. Often all that is needed to differentiate nonepileptic paroxysmal disorders from epilepsy is a careful and detailed history in addition to a thorough exam; but sometimes an electroencephalogram (EEG) or more advanced testing may be necessary. The ready availability of video recording on mobile phones and other devices at home or at school can provide invaluable information. Nonepileptic paroxysmal disorders can be classified according to the age of presentation and the clinical manifestations: (1) syncope and other generalized paroxysms, (2) movement disorders and other abnormal movements and postures, (3) oculomotor abnormalities and visual hallucinations, and (4) sleep-related disorders (Table 594-1).

SYNCOPE AND OTHER GENERALIZED PAROXYSMS

Apnea

Apneic episodes in neonates are usually associated with bradycardia as is usually apnea resulting from brainstem compression. In contrast, apnea associated with seizures is usually accompanied by tachycardia. Of note, exceptions do occur as bradycardia can occur during epileptic seizures, and severe apnea of any cause can be followed by anoxic seizures.
Breath-Holding Spells

The term breath-holding spells is actually a misnomer, as these are not self-induced, but result from the immaturity of the autonomic system and occur in 2 different forms. The first type is the pallid breath-holding spell, which is caused by reflex vagal–cardiac bradycardia and asystole. The second type is the cyanotic, or "blue," breath-holding spell, which does not occur during inspiration, but results from prolonged expiratory apnea and intrapulmonary shunting. Episodes usually start with a cry (often, in the case of the pallid type, a "silent" cry with marked pallor), and progress to apnea and cyanosis. Spells usually begin between 6 and 18 mo of age. Syncope, tonic posturing, and even reflex anoxic seizures may follow the more-severe episodes, particularly in breath-holding spells of the pallid type. Injury, anger, and frustration, particularly with surprise, are common triggers. Education and reassurance of the parents is usually all that is needed, as these episodes are, as a rule, self-limited and are outgrown within a few years. However, treatment of coexisting iron deficiency is needed if it is present as the spells are made worse by iron-deficiency anemia. Anticholinergic drugs (e.g., atropine sulfate 0.01 mg/kg/24 hr in divided doses with a maximum daily dose of 0.4 mg), or antiepileptic drug therapy for coexisting anoxic seizures that are recurrent and not responding to other measures may, rarely, be needed. It is important also to educate parents on how to handle more-severe spells by first-aid measures, or even basic CPR when needed. In severe cases of asystole, a cardiac pacemaker implantation may be needed. All parents should be taught not to provide secondary gain when the episodes occur, because this can reinforce the episodes. Also, preparation for unpleasant experiences (such as receiving a shot) rather than surprising the child with them, can help limit the number of spells (see Chapter 69).

Compulsive Valsalva

In children with intellectual disability, including Rett syndrome, syncopeal convulsions may be self-induced by maneuvers like Valsalva. In this case, true breath-holding occurs, and it usually lasts for approximately 10 sec during inspiration. Some clinicians advocate the use of naloxone in such cases.

Neurally Mediated Syncope

Syncope can present with drop attacks and can also lead to generalized convulsions, termed anoxic seizures. These convulsions, triggered by a sudden reduction of oxygen to the brain, are clinically similar to and can be misdiagnosed as generalized epileptic seizures. Vasovagal (neu-rocadiogenetic) syncope is one of the most common mimickers of generalized tonic–clonic seizures and is usually triggered by dehydration, heat, standing for a long time without movement, hot showers, the sight of blood, pain, swallowing, vomiting, and or sudden stress. History is usually the clue to distinguishing syncope from epileptic seizures: There is initially pallor and sweating followed by blurring of vision, dizziness, nausea, and then gradual collapse with loss of consciousness. These symptoms are present in most, although not necessarily all patients with syncope and can sometimes be manifestations of complex partial seizures. Much more important is the fact that such prodromal features have an insidious onset and build up gradually, often arising from a state of malaise when they precede syncope. However when they precede an epileptic convulsion, such features usually start suddenly are short in duration, paroxysmal and are followed by other manifestations of complex partial seizures such as stereotyped automatisms. Abdominal pain, a common aura in vasovagal syncope. These occur with a frequency of 10% and 50%, respectively. Postictal confusion only rarely occurs, and the rule is the occurrence of only brief postictal tiredness with a subsequent remarkable ability to resume planned activities. Most children with vasovagal syncope have an affected 1st-degree relative; reports demonstrate
autosomal dominant inheritance at least in some families. The EEG is normal and the tilt test has been used for diagnostic purposes in selected cases. In most cases with typical history, this test is not needed.

**Vagovagal syncope** can progress to convulsive seizure if the asystole is sufficiently prolonged. Sudden cold exposure to the face or to the body can also trigger vagal syncope. Syncope has been reported (rarely) to occur in association with cough, tight hair braiding, and hair combing. Orthostatic hypotension and orthostatic intolerance manifest symptoms that develop during upright standing and can be relieved by recumbence. **Postural tachycardia syndrome**, the pathophysiology of which presumably involves an excessive sympathetic discharge resulting in increased heart rate and vasoconstriction that can lead to decreased peripheral perfusion, is usually a disease of adolescent females that is characterized by upright syncope/near syncope, and tachycardia with normal or even increased blood pressure during the episode. Primary autonomic failure is rare in children, and familial dysautonomia is the only relatively common form. Familial dysautonomia is a disease common in Ashkenazi Jews and is characterized by absence of overflow emotional tears, depressed patellar reflexes, and lack of a flare reaction following intradermal histamine. Dopamine β-hydroxylase deficiency is a very rare cause of primary autonomic failure, and is characterized by a complicated perinatal course (hypotension, hypotonia, hypothermia), ptosis, highly arched palate, hyperflexible joints, impaired ejaculation, and nocturia. The tilt test causes a drop in both blood pressure and heart rate in patients with classic vasovagal syncope. It results in a blood pressure drop with minimal change in heart rate in autonomic failure, and in blood pressure drop and an increase in heart rate in postural tachycardia syndrome. Management of syncope centers on avoidance of precipitating factors (maintenance of hydration, avoidance of standing still, rising slowly from sitting, first-aid measures, raising of the legs, positioning) and treatment of any accompanying or underlying medical conditions (anemia, adrenal insufficiency, cardiac, etc.). In addition, salt supplementation (2-4 g/day), β-blockers (e.g., metoprolol at a starting dose of 1-2 mg/kg once per day up to a maximum of 6 mg/kg/day), or fluoroxyhydrocortisone (0.05-0.1 mg/day) therapy may be needed in selected cases.

**Cardiac Syncope**

See Chapter 435.5.

Long QT syndromes (LQT) can cause life-threatening “palp’d” or white syncope. Accompanying this are ventricular arrhythmias, usually torsades de pointes or even ventricular fibrillation. There are more than 10 types of prolonged QT syndrome. When accompanied by congenital deafness, it is part of the autosomal recessive Jervell and Lange-Nielson syndrome (type 1, LQT 1, associated with KvLQT1 potassium channel mutation). The Romano-Ward syndrome is an autosomal dominant syndrome with incomplete penetrance that is characterized by episodes of lying still like a dead body for several seconds before the anoxic convulsive episode. Primary autonomic failure is rare in children, and familial dysautonomia is the only relatively common form. Familial dysautonomia is a disease common in Ashkenazi Jews and is characterized by absence of overflow emotional tears, depressed patellar reflexes, and lack of a flare reaction following intradermal histamine. Dopamine β-hydroxylase deficiency is a very rare cause of primary autonomic failure, and is characterized by a complicated perinatal course (hypotension, hypotonia, hypothermia), ptosis, highly arched palate, hyperflexible joints, impaired ejaculation, and nocturia. The tilt test causes a drop in both blood pressure and heart rate in patients with classic vasovagal syncope. It results in a blood pressure drop with minimal change in heart rate in autonomic failure, and in blood pressure drop and an increase in heart rate in postural tachycardia syndrome. Management of syncope centers on avoidance of precipitating factors (maintenance of hydration, avoidance of standing still, rising slowly from sitting, first-aid measures, raising of the legs, positioning) and treatment of any accompanying or underlying medical conditions (anemia, adrenal insufficiency, cardiac, etc.). In addition, salt supplementation (2-4 g/day), β-blockers (e.g., metoprolol at a starting dose of 1-2 mg/kg once per day up to a maximum of 6 mg/kg/day), or fluoroxyhydrocortisone (0.05-0.1 mg/day) therapy may be needed in selected cases.

**Other Causes of Syncope**

Syncope that is not neurally mediated or cardiac in origin is caused by a decrease in blood volume, or a mechanical disruption of brain perfusion. Systemic diseases that lead to syncope by affecting blood volume (e.g., adrenal insufficiency) are usually first brought to medical attention by other accompanying signs and symptoms. In **stretch syncope**, which occurs mostly in adolescents while stretching the neck and the trunk backward and the arms outward, or during flexion of the neck, the presumed mechanism is mechanical disruption of brain perfusion caused by compression of the vertebral arteries. In some cases, this may be associated with an abnormally prolonged stylomastoid process compressing the carotids. If the latter condition is suspected, then neuroimaging (CT, MRI) is required for proper diagnosis of the stylomastoid anomaly.

**Sporadic and Familial Hemiplegic Migraine**

This is a rare type of migraine with a motor aura of weakness. Attacks begin as early as 5-7 yr of age. In a genetically susceptible person, attacks may be precipitated by head trauma, exertion, or emotional stress. The 3 genes so far identified are SCN1A (neuronal sodium channel subunit), CACNA1A (neuronal calcium channel subunit), and ATP1A2 (sodium potassium adenosine triphosphatase subunit). However at least a quarter of the affected families, and most of the sporadic cases do not carry a mutations in these 3 genes. Headaches occur in all attacks in most patients. The presence of negative phenomena (e.g., numbness, visual scotomas) in addition to positive phenomena (pins and needles, flickering lights), and the progressive and successive occurrence of visual, sensory, motor, aphasic, and basilar signs and symptoms, in that order, help differentiate these attacks from epileptic seizures. Persistent cerebellar deficits (e.g., nystagmus, ataxia) may be present. Verapamil, acetazolamide, and lamotrigine have been successfully used to prevent attacks and verapamil and ketamine have been used for the acute episode, while ergot derivatives, nimodipine, Midrin (isometheptene mucate, dichloralphenazone, and paracetamol), and probably triptans and propranolol are to be avoided because of concerns of exacerbating the attacks. Interestingly, the co-occurrence of epileptic seizures has been reported in a minority of patient with hemiplegic migraine. It is important also to note that recurrent attacks akin to hemiplegic migraine can be symptomatic of Sturge-Weber syndrome or various metabolic diseases (e.g., mitochondrial encephalopathy with lactic acidosis and stroke-like episodes).

**Benign Paroxysmal Vertigo of Childhood**

This is a common migraine equivalent that consists of brief seconds-to-minutes episodes of vertigo that is often accompanied by postural imbalance and nystagmus. It is important to note that vertigo does not always refer to a spinning motion; it can also refer to a backward or forward motion (vertigo titubant) where children sometimes report that objects are moving toward them. The child appears frightened during the episode. Diaphoresis, nausea, vomiting, and, rarely, tinnitus may be present. Episodes usually remit by 6 yr of age. MRI and EEG are normal, but caloric testing, if done, can show abnormal vestibular function. Diphenhydramine, 5 mg/kg/day (maximum of 300 mg/day) may be used for a cluster of attacks. Preventive therapy with cyproheptadine may be rarely needed for frequent attacks.

**Cyclic Vomiting Syndrome**

This syndrome is another related periodic migraine variant that can respond to antimigraine or antiepileptic drugs. This and other periodic syndromes have been associated with mutations that also can cause hemiplegic migraine.

**The “Alice in Wonderland” Syndrome**

This is the episodic experience of transient distortions of body image or visual images that, most often, constitute a migraine equivalent. It also can be an epileptic phenomenon.
**Migraine-Induced Syncope**

Migraine, usually of the basilar variety, can trigger vasovagal syncope and, less commonly, epileptic seizures. Careful elicitation of the history of a migrainous prelude to the syncope helps in identifying these phenomena.

**Psychogenic Disorders**

Psychogenic non-epileptic seizures are conversion reactions that are usually suspected clinically based on the characteristics of the spells (Table 594-2). The diagnosis can be confirmed by video EEG with capture of an episode to eliminate any residual doubts about their nature, as they can often occur in patients who also have epileptic seizures. They are best managed acutely by reassurance about their relatively benign nature and by a supportive attitude while at the same time avoiding positive reinforcement of the episodes. Psychiatric evaluation and follow-up are needed to uncover underlying psychopathology, and to establish continued support as psychogenic seizures can persist over long periods of time. Malingering and factitious disorder imposed on another (formerly called Munchausen syndrome by proxy) are often difficult to diagnose but an approach similar to that for psychogenic seizures, including video-EEG monitoring, is often helpful.

**Paroxysmal Extreme Pain Disorder**

Paroxysmal extreme pain disorder was previously called familial rectal pain syndrome. This syndrome (caused by the SCN9A sodium channel gene mutation) usually starts in the neonatal period or infancy and persists throughout life. Autonomic manifestations predominate initially, with skin flushing in all cases and harlequin color change and, less commonly, epileptic seizures. They are best managed acutely by reassurance about their truly epileptic nature, as they can often occur in patients who also have epileptic seizures. Careful elicitation of the history of a migrainous prelude to the syncope helps in identifying these phenomena.

**Autonomic Storms (Diencephalic Seizures)**

Spells of hyperhidrosis, changes in blood pressure, temperature and autonomic instability occur in patients with severe diffuse brain injury or localized hypothalamic injury and have been termed autonomic storms. The term diencephalic seizures is discouraged as these are not truly seizures. Therapy is difficult and has included, with mixed results, clonidine, anticonvulsants, cyproheptadine, morphine, and sympatholysis. Serotonin syndrome caused by antidepressants, stimulants, opioids, certain herbs like St. John's Wart and some other medications can produce similar symptoms, and if not recognized, can at times be fatal as can be the similar neuroleptic malignant syndrome caused by antipsychotic medications.

**MOVEMENT DISORDERS AND OTHER ABNORMAL MOVEMENTS AND POSTURES**

**Neonatal Jitteriness and Clonus**

Jitteriness consists of equal backward and forward movements of limbs, occurring spontaneously, or triggered by touch or loud sounds. Movement suppression by stimulus removal or by relaxing the affected limbs, the lack of autonomic symptoms, and the clear difference from the 2-phased (fast contraction, slow relaxation) clonic activity and the very quick myoclonic jerks, point to a nonepileptic event.
Hypocalcemia, hypoglycemia, drug withdrawal, and hypoxic–ischemic encephalopathy are possible etiologies. Clonus as a result of corticospinal tract injury usually occurs in later infancy and childhood and can be stopped by change in position.

**Paroxysmal Dyskinesias and Other Movement Disorders**

These disorders are characterized by sudden attacks that consist of choreic, dystonic, ballistic, or mixed movements (Table 594-3). A sensation of fatigue or weakness confined to 1 side may herald an attack. Consciousness is preserved and patients may be able perform a motor activity, like walking, despite the attack. The variability in the pattern of severity and localization between different attacks may also help in differentiating them from seizures. The frequency of attacks increases in adolescence, and steadily decreases in the 3rd decade. Neurologic exam between attacks, EEG, laboratory investigations, and imaging studies are normal. These dyskinesias often respond to phenytoin, carbamazepine, clonazepam, or to antidopaminergic drugs such as haloperidol. Drug reactions can result in abnormal movements such as oculogyric crisis with many antiepileptics, choreoathetosis with phenytoin, dystonia and facial dyskinesias with antidopaminergic drugs, and tics with carbamazepine. Strokes, focal brain lesions, connective tissue disorders (e.g., systemic lupus erythematosus), vasculitis, or metabolic and genetic disorders can also cause movement disorders. Mutations of the glucose transporter 1 (GLUT1/SLC2A1) gene have been described in patients with exercise-induced dyskinesia.

**Motor Tics**

These are movements that are under partial control, and are associated with an urge to do them and with a subsequent relief. They are usually exacerbated by emotions, and often change in character over time. In patients with tics who have Tourette syndrome, there is often a family history of tics and/or obsessive compulsive disorder or personality traits.

**Episodic Ataxias**

Episodic ataxia encompasses 7 clinically and genetically heterogeneous syndromes, only 2 of which (types 1 and 2) have been described in a large number of families. Type 1 is caused by mutations in the voltage-gated potassium channel Kv1.1. It consists of brief episodes (seconds to minutes) of cerebellar ataxia, and occasional partial seizures with interictal myokymia as a main diagnostic feature. Type 2 is characterized by longer attacks (minutes to hours) and interictal cerebellar signs. It is caused by mutations in the voltage-gated calcium channel gene CACNA1A. This type is more responsive than type 1 to acetazolamide that reduces the frequency and severity of attacks, but not the interictal signs and symptoms.

**Benign Myoclonus of Early Infancy, Shuddering Attacks, and Chin Trembling**

Benign myoclonus consists of myoclonic jerks of the extremities in wakefulness and sometimes also in sleep. It has been suggested by some that these attacks are in the same spectrum as shuddering attacks. Shuddering attacks are characterized by rapid tremor of the head, shoulder, and trunk, lasting a few seconds, often associated with eating, and recurring many times a day. Others have considered shuddering as an early manifestation of essential tremor as family history of essential tremor is often present. The clinical events in either of these can be mistaken for infantile spasms, but ictal and interictal EEG, MRI, and development are normal. Spontaneous remission occurs in both usually within a few months. Hereditary chin trembling at a frequency faster than 3 Hz starting shortly after birth and precipitated by stress has been described in several families.

A novel type of nonepileptic attack with infantile onset characterized in 3 patients as clusters of repeated head drops, mimicking epileptic negative myoclonus of the neck, accompanied by crying. The episodes occurred for 5 or 6 mo and disappeared by the end of the 1st yr. Language and cognition were normal. This is a different form of myoclonic activity that may complicate the diagnosis of infantile spasms and West syndrome; thorough EEG investigation is needed in such cases.

**Brainstem Dysfunction**

Decorticate or decerebrate posturing that mimics epileptic tonic seizures may be secondary to decompensated hydrocephalus,

Psychologic Disorders

Many psychologic disorders can be mistaken for epileptic seizures. Pleasurable behavior similar to masturbation may occur from infancy onward, and may consist of rhythmic rocking movement in a sitting or lying position, or rhythmic hip flexion and adduction. Masturbation may occur in girls 2-3 yr of age and is often associated with perspiration, irregular breathing, and grunting, but no loss of consciousness. Occasionally this is associated with child abuse or with other psychopathology. Stereotypies, or repetitive movements that are more complex than tics and do not change and wax and wane like tics (e.g., head banging, head rolling, body rocking, and hand flapping), usually occur in neurologically impaired children. A mannerism is a pattern of socially acceptable, situationsal behavior that is seen in particular situations such as gesturing when talking. Mannerisms should not be confused with stereotypies which are generally pervasive over almost every other activity such as head-shaking or hand-flapping in multiple situations. Stereotypies, unlike mannerisms, increase with stress. Unlike tics and mannerisms, stereotypies usually start before the age of 3 yr, involve more body parts, are more rhythmic and most importantly occur with engagement with an object or activity of interest and do not have a premonitory urge that increases with attempts to suppress them as children rarely try to suppress stereotypies. Panic and anxiety attacks have been described in children; at times, these may be clinically indistinguishable from actual epileptic seizures, and therefore may necessitate video–EEG monitoring. Rage attacks usually occur in patients with personality disorder and are usually not seizures although rare cases of partial seizures can manifest as rage attacks. Hyperventilation spells can be precipitated by anxiety and are associated with dizziness, tingling, and, at times, carpopedal spasm. Transient global amnesia consists of isolated short-term memory loss for minutes to hours that occurs mostly in the elderly. The etiology can be epileptic, vascular, or drug related.

Oculomotor Apraxia and Saccadic Intrusions

In oculomotor apraxia saccadic eye movements are impaired. Sudden head turns compensating for lateral gaze impairment mimic seizures. This disorder may be idiopathic (Cogan oculomotor apraxia) or may occur in the context of ataxia telangiectasia or lysosomal storage diseases. Genetic defects in DNA repair mechanisms have been implicated in at least 4 spino cerebellar ataxia disorders that are accompanied by oculomotor apraxia. A selective loss of Purkinje cells required to suppress omnipause neurons and initiate saccadic eye movement is believed to occur in these disorders. Saccadic intrusions are involuntary sudden conjugate eye movements away from the desired eye position. These are not necessarily pathologic.

Spasmus Nutans

This disorder presents with a triad of nystagmus, head tilt, and head nodding. If diurnal fluctuation occurs, symptoms may look like epileptic seizures. Brain MRI should be performed, as the triad has been...
associated with masses in the optic chiasm and third ventricle. Retinal
disease should also be ruled out. In the absence of these associations,
remission occurs before 5 yr of age.

**Opsoclonus Myoclonus Syndrome**
The so-called dancing eyes refers to continuous, random, irregular, and
conjugate eye movements that may fluctuate in intensity. They usually
accompany myoclonus and ataxia ("dancing feet"). Encephalitis and
neuroblastoma are possible causes. Therapy is by treating the underly-
ing etiology, but adrenocorticotropic hormone (ACTH), corticoster-
roids, and clonazepam may be needed. Rituximab has been studied and
preliminary trials suggest it may be effective as well.

**Daydreaming and Behavioral Staring**
Staring may be a manifestation of absence seizures, which should be
differentiated from daydreaming, behavioral staring because of fatigue,
and inattention. Episodes of staring only in certain settings (e.g.,
school) are unlikely to be seizures. In addition, responsiveness to stim-
ulation such as touch and lack of interruption of playing activity char-
acterizes nonepileptic staring.

**Visual Hallucinations**
Visual perceptions in the absence of external stimuli, or visual hallu-
cinations, are usually accompanied by other neurologic signs and
symptoms when they occur in the context of seizures. An exception is
occipital seizures, which can manifest with isolated and unformed
visual hallucinations and may be accompanied by headache and
nausea, making them difficult to differentiate from migraine. However,
occipital seizures are characterized by colorful, shapes, circles and
spots lasting seconds and confined to 1 hemifield, while migrainous
auras usually last minutes, and consist of black-and-white lines, scoto-
mas, and or fortification spectra that start in the center of vision. Hal-
 lucinations can also be secondary to drug exposure, midbrain lesions,
and psychiatric illnesses. In addition, retinal-associated hallucinations
can occur in the form of flashes of light in the context of inflammatory
etiologies, trauma, or optic nerve edema.

**SLEEP DISORDERS**
Paroxysmal nonepileptic sleep events are more common in epileptic
patients than in the general population, which makes their diagnosis
difficult. Semiology, timing of events, and if needed video-EEG and
polysomnography help in distinguishing epileptic from nonepileptic
events. Parasomnias typically occur less than once or twice a night;
more frequent episodes suggest epileptic seizures. Of note, the EEG
pattern of frontal lobe epileptic seizures may be similar to the one seen
in a normal arousals, making their diagnosis challenging, especially
that they have nonspecific hypermotor manifestations such as thrash-
ing, body rocking, kicking, boxing, pedaling, bending, running, and
various vocalizations. The diagnosis of such epileptic seizures is made
on the basis of highly stereotyped events arising several times a night
from nonrapid eye movement sleep.

**Benign Sleep Myoclonus and
Neonatal Sleep Myoclonus**
Neonatal sleep myoclonus consists of repetitive, usually bilateral rhyth-
mic jerks involving the upper and lower limbs during nonrapid eye
movement sleep, sometimes mimicking clonic seizures. A slow (1 Hz)
rocking of the infant in a head-to-toe direction is a specific diagnostic
test that may reproduce the myoclonus. The lack of autonomic changes,
occurance only in sleep, and suppression by awakenings may help in
differentiating these events from epileptic seizures. Remission is spon-
taneous at 2-3 mo of age. In older children and adults, sleep myoclonus
consists of random myoclonic jerks of the limbs.

**Nonrapid Eye Movement Partial
Arousal Disorders**
Brief nocturnal confusional arousals occurring 1-2 hr after sleep in
stage 4 sleep are normal in children. Such episodes can vary from
chewing, sitting up, and mumbling to agitated sleep walking, and
usually last for 10-15 min. **Night terrors** similarly occur a few hours
after going to sleep in stage 3 or 4 of sleep, most often at 2-7 yr of age
and more so in boys. The child screams; appears terrified; has dilated
pupils, tachycardia, tachynea, unresponsiveness, agitation, and
thrashing that increase with attempts to be consoled; is difficult to
arouse; and may have little or no vocalization. In older children with
persistent night terrors, an underlying psychologic etiology may be
present. Diagnosis is based on the history. However, rarely, video EEG
monitoring may be needed. At times, the use of bedtime diazepam
(0.2-0.3 mg/kg) or clonazepam (0.01 mg/kg) may help control the
problem while psychologic factors are being investigated. **Restless leg
syndrome** can cause painful leg dysesthesias that cause nocturnal
arousals and insomnia. It can be either genetic or associated with iron
deficiency, systemic illness, or some drugs. Therapy depends upon
treating the underlying cause and, if needed, on dopaminergic drugs
such as levodopa/carbidopa, or antiepileptics like gabapentin.

**Rapid Eye Movement Sleep Disorders**
Nightmares and sleep paralysis are common disorders. Unlike night
terrors, nightmares tend to occur later during the night and the child
has a memory of the event.

**Sleep Transition Disorders**
Nocturnal head banging (**jactatio capitis nocturna**), rolling, or body
rocking often occurs in infants and toddlers as they are trying to fall
asleep. These usually remit spontaneously by 5 yr of age. No specific
therapy is needed.

**Narcolepsy-Catatlexy Syndrome**
Narcolepsy is characterized by excessive daytime sleepiness, cataplexy,
sleep paralysis, hypnagogic hallucinations, and disturbed nighttime
sleep. The persistence of rapid eye movement sleep atonia upon awak-
ening or its intrusion during wakefulness lead to sleep paralysis or
catatlexy, respectively. Loss of tone in cataplexy occurs in response to
strong emotions, and spreads from the face downwards leading to a
fall in a series of stages rather than a sudden one. Consciousness is
maintained in cataplexy. A selective loss of hypocretin-secreting
neurons in the hypothalamus is at the origin of this disorder. The fact
that DQB1*0602 is a predisposing HLA allele identified in 85-95% of
patients with narcolepsy-cataplexy suggests an autoimmune-mediated
neuronal loss. Diagnosis is based on the **multiple sleep latency test**, and
therapy relies on scheduled naps, amphetamines, methylpheni-
date, tricyclic antidepressants, and counseling about precautions in
work and driving.

**Bibliography is available at Expert Consult.**
Bibliography

Headache is a common complaint in children and adolescents. Headaches can be a primary problem or occur as a symptom of another disorder, representing a secondary problem. Recognizing this difference is essential for choosing the appropriate evaluation and treatment to ensure successful management of the headache. Primary headaches are most often recurrent, episodic headaches and for most children are sporadic in their presentation.

The most common forms of primary headache of childhood are migraine and tension-type headaches (Table 595-1). Other forms of

Medication-Overuse Headache (MOH)

Ergotamine-overuse headache

Triptan-overuse headache

Simple analgesic-overuse headache

Paracetamol (acetaminophen)-overuse headache

Acetamisalicic acid-overuse headache

Other non-steroidal antiinflammatory drug (NSAID)-overuse headache

Opioid-overuse headache

Combination analgesic-overuse headache

Headache attributed to substance withdrawal

Caffeine-withdrawal headache

Opioid-withdrawal headache

Estrogen-withdrawal headache

HEADACHE ATTRIBUTED TO INFECTION

Acute or chronic headache attributed to bacterial meningitis or meningococcal infection

Persistent headache attributed to past bacterial meningitis or meningococcal infection

Acute or chronic headache attributed to intracranial fungal or other parasitic infection

Headache attributed to brain abscess

Headache attributed to subdural empyema

Headache attributed to systemic infection (acute or chronic)

HEADACHE ATTRIBUTED TO DISORDER OF HOMEOSTASIS

Headache attributed to hypoxia and/or hypercapnia

High-altitude headache

Headache attributed to airplane travel

Diving headache

Sleep apnea headache

Dialysis headache

Headache attributed to arterial hypertension

Headache attributed to pheochromocytoma

Headache attributed to hypertensive crisis with or without hypertensive encephalopathy

Headache attributed to preeclampsia or eclampsia

Headache attributed to autonomic dysreflexia

Headache attributed to hypothyroidism

Headache attributed to fasting

Cardiac cephalalgia

Headache attributed to other disorder of homeostasis

HEADACHE or FACIAL PAIN attributed to disorder of the cranium, neck, eyes, ears, nose, sinuses, teeth, mouth, or other facial or cervical structure

Headache attributed to disorder of cranial bone

Headache attributed to retropharyngeal tendinitis

Headache attributed to craniofacial dystonia

Headache attributed to acute glaucoma

Headache attributed to refractive error

Headache attributed to heterophoria or heterotropia (latent or persistent squint)

Headache attributed to ocular inflammatory disorder

Headache attributed to trachelitis

Headache attributed to disorder of the ear(s)

Headache attributed to acute or chronic or recurring rhinosinusitis

Headache attributed to temporomandibular disorder (TMD)

Headache or facial pain attributed to inflammation of the stylohyoid ligament

Headache or facial pain attributed to other disorder of cranium, neck, eyes, ears, nose, sinuses, teeth, mouth, or other facial or cervical structure

HEADACHE ATTRIBUTED TO PSYCHIATRIC DISORDER

Headache attributed to somatization disorder

Headache attributed to psychotropic disorder

PAINFUL CRANIAL NEUROPATHIES and OTHER FACIAL PAINS

Classical trigeminal neuralgia

Classical trigeminal neuralgia, purely paroxysmal or with concomitant persistent pain

Painful trigeminal neuropathy

Painful trigeminal neuropathy attributed to acute herpes zoster

Postherpetic trigeminal neuropathy

Painful posttraumatic trigeminal neuropathy

Painful trigeminal neuropathy attributed to multiple sclerosis (MS) plaque

Painful trigeminal neuropathy attributed to space-occupying lesion

Painful trigeminal neuropathy attributed to other disorder

Glossopharyngeal neuralgia

Classical nervus intermedius (facial nerve) neuralgia

Nervus intermedius neuropathy attributed to herpes zoster

Occipital neuralgia

Optic neuritis

Headache attributed to ischecnic ocular motor nerve palsy

Tolosa-Hunt syndrome

Paratrigeminal oculosympathetic (Raeder) syndrome

Recurrent painfull ophthalmoplegic neuropathy

Burning mouth syndrome (BMS)

Persistent idiopathic facial pain (PIFP)

Central neuropathic pain

Central neuropathic pain attributed to multiple sclerosis (MS)

Central post-stroke pain (CPSP)

primary headache, including the trigeminal autonomic cephalalgias, occur much less commonly. Primary headache can progress to very frequent or even daily headaches with chronic migraine and chronic tension-type headaches being increasingly recognized. These more frequent headaches can have an enormous impact on the life of the child and adolescent, as reflected in school absences and decreased school performance, social withdrawal, and changes in family interactions. To reduce this impact, a treatment strategy that incorporates acute treatments, preventive treatments, and biobehavioral therapies must be implemented.

Secondary headache involves headaches that are a symptom of an underlying illness (see Table 595-1). The underlying illness should be clearly present as a direct cause of the headaches. This is often difficult when 2 or more common conditions occur in close temporal association. This frequently leads to the misdiagnosis of a primary headache as a secondary headache. This is, for example, the case when migraine is misdiagnosed as a sinus headache. In general, the key components of a secondary headache are the likely direct cause-and-effect relationship between the headache and the precipitating condition, and the lower likelihood in a specific patient and circumstance of the headaches being the result of a recurrent headache disorder. In addition, once the underlying suspected cause is treated, the secondary headache should resolve. If this does not occur, either the diagnosis must be reevaluated or the effectiveness of the treatment reassessed. One key clue that additional investigation is warranted is the presence of an abnormal neurologic examination or unusual neurologic symptoms.
595.1 Migraine
Andrew D. Hershey, Marielle A. Kabbouche, and Hope L. O’Brien

Migraine is the most frequent type of recurrent headache that is brought to the attention of parents and primary care providers, but it remains underrecognized and undertreated, particularly in children. Migraine is characterized by episodic attacks that may be moderate to severe in intensity, focal in location on the head, have a throbbing quality, and may be associated with nausea, vomiting, light sensitivity, and sound sensitivity. Compared to adults, pediatric migraine is shorter in duration and has a bilateral, often bifrontal, location. Migraine can also be associated with an aura that may be typical (visual, sensory, or dysphasic) or atypical (i.e., hemiplegic, “Alice in Wonderland” syndrome) (Tables 595-2 to 595-6). In addition, a number of migraine variants have been described and, in children, include abdominal related symptoms without headache, and components of the painless periodic syndromes of childhood (see Table 595-1). Treatment of migraine requires the incorporation of an acute treatment plan, a preventive treatment plan if the migraine occurs frequently or is disabling, and a biobehavioral plan to help cope with both the acute attacks and frequent or persistent attacks if present.

EPIDEMIOLOGY
Up to 75% of children report having a significant headache by the time they are 15 yr old. Recurrent headaches are less common, but remain highly frequent. Migraine has been reported to occur in up to 10.6% of children between the ages of 5 and 15 yr, and up to 28% of older children between the ages of 5 and 15 yr. Migraine has been reported to occur in up to 10.6% of children by the time they are 15 yr old.

### Table 595-2 Migraine Without Aura

| A. At least 5 attacks fulfilling criteria B to D |
| B. Headache attacks lasting 4-72 hr (untreated or unsuccessfully treated) |
| C. Headache has at least 2 of the following 4 characteristics: |
| 1. Unilateral location |
| 2. Pulsating quality |
| 3. Moderate or severe pain intensity |
| 4. Aggravation by or causing avoidance of routine physical activity (e.g., walking or climbing stairs) |
| D. During headache at least 1 of the following: |
| 1. Nausea and/or vomiting |
| 2. Photophobia and phonophobia |
| E. Not better accounted for by another ICHD-3 diagnosis |

### Table 595-3 Migraine with Typical Aura

| A. At least 2 attacks fulfilling criteria B and C |
| B.Aura consisting of visual, sensory and/or speech/language symptoms, each fully reversible, but no motor, brainstem or retinal symptoms |
| C. At least 2 of the following 4 characteristics: |
| 1. At least 1 aura symptom spreads gradually over 5 or more minutes, and/or 2 or more symptoms occur in succession |
| 2. Each individual aura symptom lasts 5-60 minutes |
| 3. At least 1 aura symptom is unilateral |
| 4. The aura is accompanied, or followed within 60 minutes, by headache |
| D. Not better accounted for by another ICHD-3 diagnosis, and transient ischemic attack has been excluded |

### Table 595-4 Migraine with Brainstem Aura

| A. At least 2 attacks fulfilling criteria B to D |
| B. Aura consisting of visual, sensory and/or speech/language symptoms, each fully reversible, but no motor or retinal symptoms |
| C. At least 2 of the following brainstem symptoms: |
| 1. Dysarthria |
| 2. Vertigo |
| 3. Tinnitus |
| 4. Hypacusis |
| 5. Diplopia |
| 6. Ataxia |
| 7. Decreased level of consciousness |
| D. At least 2 of the following 4 characteristics: |
| 1. At least 1 aura symptom spreads gradually over 5 or more minutes, and/or 2 or more symptoms occur in succession |
| 2. Each individual aura symptom lasts 5-60 minutes |
| 3. At least 1 aura symptom is unilateral |
| 4. The aura is accompanied, or followed within 60 minutes, by headache |
| E. Not better accounted for by another ICHD-3 diagnosis, and transient ischemic attack has been excluded |

### Table 595-5 Vestibular Migraine with Vertigo

| A. At least 5 episodes fulfilling criteria C and D |
| B. A current or past history of 1.1 Migraine without aura or 1.2 Migraine with aura |
| C. Vestibular symptoms of moderate or severe intensity, lasting between 5 min and 72 hr |
| D. At least 50% of episodes are associated with at least 1 of the following 3 migrainous features: |
| 1. Headache with at least 2 of the following 4 characteristics: |
| a. Unilateral location |
| b. Pulsating quality |
| c. Moderate or severe pain intensity |
| d. Aggravation by routine physical activity |
| 2. Photophobia and phonophobia |
| 3. Visual aura |
| E. Not better accounted for by another ICHD-3 diagnosis or by another vestibular disorder |

### Table 595-6 Chronic Migraine

| A. Headache (tension-type-like and/or migraine-like) on 15 or more days per month for more than 3 mo and fulfilling criteria B and C |
| B. Occurring in a patient who has had at least 5 attacks fulfilling criteria B to D for 1.1 Migraine without aura and/or criteria B and C for 1.2 Migraine with aura |
| C. On 8 or more days per month for more than 3 mo, fulfilling any of the following: |
| 1. Criteria C and D for 1.1 Migraine without aura |
| 2. Criteria B and C for 1.2 Migraine with aura |
| 3. Believed by the patient to be migraine at onset and relieved by a triptan or ergot derivative |
| D. Not better accounted for by another ICHD-3 diagnosis |

adolescents. When the headaches become frequent, they convert into chronic daily headaches in up to 1% of children. When headaches are occurring more than 15 days a month the risk of conversion to a daily headache becomes more prominent. This explains the necessity to treat the headaches aggressively or prevent the headaches altogether, trying to block transformation to chronic daily headaches.

Migraine can impact a patient’s life through school absences, limitation of home activities, and restriction of social activities. As headaches become more frequent, their negative impact increases in magnitude. This can lead to further complications including anxiety and school avoidance, requiring a more extensive treatment plan.

**CLASSIFICATION AND CLINICAL MANIFESTATIONS**

Criteria have been established to guide the clinical and scientific study of headaches; these are summarized in *The International Classification of Headache Disorders*, 3rd edition (ICHD-3 beta). Table 595-1 contrasts the different clinical types of migraine; Tables 595-2 to 595-6 list the specific criteria for migraine types.

**Migraine Without Aura**

Migraine without aura is the most common form of migraine in both children and adults. The ICHD-3 beta (see Table 595-2) requires this to be recurrent (at least 5 headaches that meet the criteria, but there is no time limit over which this must occur). The recurrent episodic nature helps differentiate this from a secondary headache, as well as separates migraine from tension-type headache, but may limit the diagnosis in children as they may just be beginning to have headaches.

The duration of the headache is defined as 4-72 hr for adults. It has been recognized that children may have shorter-duration headaches, so an allowance has been made to reduce this duration to 2-72 hr or 1-72 hr with diary confirmation. Note that this duration is for the untreated or unsuccessfully treated headache. Furthermore, if the child falls asleep with the headache, the entire sleep period is considered part of the duration. These duration limits help differentiate migraine from both short-duration headaches, including the trigeminal autonomic cephalalgias, and prolonged headaches, like those caused by idiopathic intracranial hypertension (pseudotumor cerebri). Some prolonged headaches may still be migraine, but a migraine that persists beyond 72 hr is classified as a variant termed status migrainosus.

The quality of migraine pain is often, but not always, throbbing or pounding. This may be difficult to elicit in young children and drawings or demonstrations may help confirm the throbbing quality.

The location of the pain has classically been described as unilateral (hemicrania); in young children it is more commonly bilateral. A more appropriate way to think of the location would therefore be focal, to differentiate it from the diffuse pain of tension-type headaches. Of particular concern is the exclusively occipital headache because although these can be migraines, they are more frequently secondary to another more proximate etiology such as posterior fossa abnormalities.

Migraine, when allowed to fully develop, often worsens in the face of and secondarily results in altered activity level. For example, worsening of the pain occurs classically in adults when going up or down stairs. This history is often not elicited in children. A change in the child’s activity pattern can be easily observed as a reduction in play or physical activity. Older children may limit or restrict their sports activities or exercise during a headache attack.

Migraine may have a variety of associated symptoms. In younger children, nausea and vomiting may be the most obvious symptoms and often outweigh the headache itself. This often leads to the overlap with several of the gastrointestinal periodic diseases, including recurrent abdominal pain, recurrent vomiting, cyclic vomiting, and abdominal migraine. The common feature among all of these related conditions is an increased propensity among children with them for the later development of migraine. Oftentimes, early childhood recurrent vomiting may in fact be migraine, but the child is not asked about or is unable to describe headache pain. Once this becomes clear, the earlier diagnosis of a gastrointestinal disorder is no longer appropriate. When headache is present, vomiting raises the concern of a secondary headache, particularly related to increased intracranial pressure. One of the red flags for this is the daily or near daily early morning vomiting, or headaches waking the child up from sleep. When the headaches associated with vomiting episodes are sporadic and not worsening, it is more likely that the diagnosis is migraine. Vomiting and headache caused by increased intracranial pressure are frequently present on first awakening and remit with maintenance of upright posture. In contrast, if a migraine is present on first awakening (a relatively infrequent occurrence in children), getting up and going about normal, upright activities usually makes the headache and vomiting worse.

As the child matures, light and sound sensitivity (photophobia and phonophobia) may become more apparent. This is either by direct report of the patient, or the interpretation by the parents of the child’s activity. These symptoms are likely a component of the hypersensitivity that develops during an acute migraine attack and may also include smell sensitivity (osmophobia) and touch sensitivity (cutaneous allodynia with central sensitization). Although only the photophobia and phonophobia are components of the ICHD-3 beta criteria, these other symptoms are helpful in confirming the diagnosis and may be helpful in understanding the underlying pathophysiology and determining the response to treatment. The final ICHD-3 beta requirement is the exclusion of causes of secondary headaches, and this should be an integral component of the headache history.

Migraine typically runs in families with reports up to 90% of children having a 1st- or 2nd-degree relative with recurrent headaches. Given the underdiagnosis and misdiagnosis in adults, this is often not recognized by the family and a headache family history is required. When a family history is not identified, this may be the result of either a lack of awareness of migraine within the family or an underlying secondary headache in the child. Any child whose family, upon close and both direct and indirect questioning, does not include individuals with migraine or related syndromes (e.g., motion sickness, cyclic vomiting, menstrual headache) should have an imaging procedure performed to look for anatomic etiologies for headache.

In addition to the classifying features, there may additional markers of a migraine disorder. These include such things as triggers (skipping meals, inadequate or irregular sleep, dehydration and weather changes are the most common), pattern recognition (associated with menstrual periods in adolescents or Monday-morning headaches resulting from changes in sleep patterns over the weekend and nonphysiologic early waking on Monday mornings for school), and premonitory symptoms (a feeling of irritability, tiredness, and food cravings prior to the start of the headache). Although these additional features may not be consistent, they do raise the index of suspicion for migraine and provide a potential mechanism of intervention. In the past, food triggers were considered widely common, but the majority have either been discredited with scientific study or represent such a small number of patients that they only need to be addressed when consistently triggering the headache.

**Migraine with Aura**

The aura associated with migraine is a neurologic warning that a migraine is going to occur. In the common forms this can be the start of a typical migraine or a headache without migraine, or it may even occur in isolation. For a typical aura, the aura needs to be visual, sensory, or dysphasic, lasting longer than 5 min and less than 60 min with the headache starting within 60 min (see Table 595-3). The importance of the aura lasting longer than 5 min is to differentiate the migraine aura from a seizure with a postictal headache, while the 60 min maximal duration is to separate migraine aura from the possibility of a more prolonged neurologic event such as a transient ischemic attack.

The most common type of visual aura in children and adolescents is photopsia (flashes of light or light bulbs going off everywhere). These photopsias are often multicolored and when gone, the child may report not being able to see where the flash occurred. Less likely in children are the typical adult auras including fortification spectra (brilliant white
CSF lymphocytosis (HaNDL) describes transient headaches associated with vertigo, tinnitus, diplopia, blurred vision, scotoma, seizures, repetitive daily episodes of blindness, cerebellar signs, and then followed in sequence by sensory, motor, aphasic, and then aura symptom and may progress slowly over 20-30 min first with visual and then followed in sequence by sensory, motor, aphasic, and then basilar auras. Headache is present in more than 95% of patients and usually begins during the aura; headache may be unilateral or bilateral and may have no relationship to the motor weakness. Some patients may develop attacks of coma with encephalopathy, cerebrospinal fluid (CSF) pleocytosis, and cerebral edema. Long-term complications may include seizures, repetitive daily episodes of blindness, cerebellar signs with the development of cerebellar atrophy, and mental retardation.

Basilar-type migraine was formerly considered a disease of the basilar artery as many of the unique symptoms were attributed to dysfunction in this area of the brainstem. Some of the symptoms described include vertigo, tinnitus, diplopia, blurred vision, scotoma, ataxia, and an occipital headache. The pupils may be dilated, and ptosis may be evident.

Syndrome of transient headache and neurologic deficits with CSF lymphocytosis (HaNDL) describes transient headaches associated with neurologic deficits, and CSF showing pleocytosis. It is considered a self-limited migraine-like syndrome, and is rarely reported in the pediatric population.

Childhood periodic syndromes are a group of potentially related symptoms that occur with increased frequency in children with migraine. The hallmark of these symptoms is the recurrent episodic nature of the events. Some of these have included gastrointestinal-related symptoms (motion sickness, recurrent abdominal pain, recurrent vomiting including cyclic vomiting, and abdominal migraine), sleep disorders (sleepwalking, sleep talking, and night terrors), unexplained recurrent fevers, and even seizures.

The gastrointestinal symptoms span the spectrum from the relatively mild (motion sickness on occasional long car rides) to severe episodes of uncontrollable vomiting that may lead to dehydration and the need for hospital admission to receive fluids. These latter episodes may occur on a predictable time schedule and hence have been called cyclic vomiting. During these attacks, the child may appear pale and frightened but does not lose consciousness. After a period of deep sleep, the child awakens and resumes normal play and eating habits as if the vomiting had not occurred. Many children with cyclic vomiting have a positive family history of migraine, and as they grow older have a higher than average likelihood of developing migraine. Cyclic vomiting may be responsive to migraine-specific therapies with careful attention to fluid replacement if the vomiting is excessive. Cyclic vomiting of migraine must be differentiated from gastrointestinal disorders including intussusception (malrotation, intermittent volvulus, duodenal web, duplication cysts, superior mesenteric artery compression, and internal hernias), peptic ulcer, gastritis, giardiasis, chronic pancreatitis, and Crohn disease. Abnormal gastrointestinal motility and pelvicvureteric junction obstruction can also cause cyclic vomiting. Metabolic causes include disorders of amino acid metabolism (heterozygote ornithine transcarbamylase deficiency), organic acidurias (propionic acidemia, methylmalonic acidemia), fatty acid oxidation defects (medium-chain acyl-coenzyme A dehydrogenase deficiency), disorders of carbohydrate metabolism (hereditary fructose intolerance), acute intermittent porphyria, and structural central nervous system lesions (posterior fossa brain tumors, subdural hematomas or effusions). The diagnosis is a diagnosis of exclusion and children will need a full work up prior to be labeled of cyclic vomiting syndrome. Cyclic vomiting syndrome is more frequent in younger children and will gradually transform into a typical migraine attack by puberty.

The diagnosis of abdominal migraine can be confusing but can be thought of as a migraine without the headache. Like a migraine, it is an episodic disorder characterized by midabdominal pain with pain-free periods between attacks. At times this pain is associated with nausea and vomiting (thus crossing into the recurrent abdominal pain or cyclic vomiting spectrum). The pain is usually described as “dull” and may be moderate to severe. The pain may persist from 1-72 hr and, although usually midline, may be periumbilical or poorly localized by the child. To meet the criteria of abdominal migraine, the child must complain at the time of the abdominal pain of at least 2 of the following: anorexia, nausea, vomiting, or pallor. As with cyclic vomiting, a thorough history and physical examination with appropriate laboratory studies must be completed to rule out an underlying gastrointestinal disorder as a cause of the abdominal pain. Careful questioning about the presence of headache or head pain needs to be addressed directly with the child, as many times this is truly a migraine, but in the child’s mind (as well as the parents’ observation) the abdominal symptoms are paramount.

**DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS**

A thorough history and physical examination including a neurologic examination with special focus on headache has been shown to be the most sensitive indicator of an underlying etiology. The history needs to include a thorough evaluation of the premonitory symptoms, any potential triggering events or timing of the headaches, associated neurologic symptoms, and a detailed characterization of the headache attacks, including frequency, severity, duration, associated symptoms, use of medication, and disability. The disability assessment should include the impact on school, home, and social activities and can easily be assessed with tools such as PEDMIDAS. Family history of headaches and any other neurologic, psychiatric, and general health conditions is also important both for identification of migraine within the family as well as the identification of possible secondary headache disorders. The familial penetrance of migraine is so robust that the absence of a family history of migraine or its equivalent phenomena should trigger obtaining of an imaging procedure. When headaches are refractory, a history of potential comorbid conditions, which includes mood disorders and
illicit substance use, especially in teenagers, that may influence adherence and acceptability of the treatment plan, may also need to be addressed.

Neuroimaging is warranted when the neurologic examination is abnormal or unusual neurologic features occur during the migraine; when the child has headaches that awaken the child from sleep or that are present on first awakening and remit with upright posture; when the child has brief headaches that only occur with cough or bending over; when the headache is mostly in the occipital area; and when the child has migrainous headache with an absolutely negative family history of migraine or its equivalent (e.g., motion sickness, cyclic vomiting; Table 595-7). In this case, an MRI is the imaging of choice as it provides the highest sensitivity for detecting posterior fossa lesions and does not expose the child to radiation.

In the child with a headache that is instantaneously at its worst at onset, a CT scan looking for blood is the best initial test; and, if it is negative, a lumbar puncture should be done looking especially for xanthochromia of the CSF. There is no evidence that laboratory studies or an electroencephalogram is beneficial in a typical migraine without aura or migraine with aura.

**TREATMENT**

Table 595-8 outlines the drugs used to manage migraine headaches in children.

The American Academy of Neurology established useful practice guidelines for the management of migraine as follows:

1. Reduction of headache frequency, severity, duration, and disability
2. Reduction of reliance on poorly tolerated, ineffective, or unwanted acute pharmacotherapies
3. Improvement in quality of life

4. Avoidance of acute headache medication escalation
5. Education and enabling of patients to manage their disease to enhance personal control of their migraine
6. Reduction of headache-related distress and psychologic symptoms

**Table 595-7** Indications for Neuroimaging in a Child with Headaches

- Abnormal neurologic examination
- Abnormal or focal neurologic signs or symptoms
  - Focal neurologic symptoms or signs developing during a headache (i.e., complicated migraine)
  - Focal neurologic symptoms or signs (except classic visual symptoms of migraine) develop during the aura, with fixed laterality; focal signs of the aura persisting or recurring in the headache phase
- Seizures or very brief auras (<5 min)
- Unusual headaches in children
  - Atypical auras including basilar-type, hemiplegic
  - Trigeminal autonomic cephalalgia including cluster headaches in child or adolescent
- An acute secondary headache (i.e., headache with known underlying illness or insult)
- Headache in children younger than 6 yr old or any child who cannot adequately describe his or her headache
- Brief cough headache in a child or adolescent
- Headache worst on first awakening or that awakens the child from sleep
- Migrainous headache in the child with no family history of migraine or its equivalent

*FDA approved in the pediatric population.
†Available in Europe.
↑, Increase; CNS, central nervous system; GABA, γ-aminobutyric acid; GI, gastrointestinal; hs, at night; SC, subcutaneous.
To accomplish these goals, 3 components need to be incorporated into the treatment plan:
1. An acute treatment strategy should be developed for stopping a headache attack on a consistent basis with return to function as soon as possible with the goal being 2 hr maximum.
2. A preventive treatment strategy should be considered when the headaches are frequent (1 or more per week) and disabling.
3. Biobehavioral therapy should be started, including a discussion of adherence, elimination of barriers to treatment, and healthy habit management.

**Acute Treatment**
Management of an acute attack is to provide headache freedom as quickly as possible with return to normal function. This mainly includes 2 groups of medicines: nonsteroidal antiinflammatory drugs (NSAIDs) and triptans. Most migraine headaches in children will respond to appropriate doses of NSAIDs when administered at the onset of the headache attack. Ibuprofen has been well documented to be effective at a dose of 7.5-10.0 mg/kg and is often preferred; however, acetaminophen (15 mg/kg) can be effective in those with a contraindication to NSAIDs. Special concern for the use of ibuprofen or other NSAIDs includes ensuring that the children can recognize and respond to onset of the headache. This means discussing with the child the importance of telling the teacher when the headache starts at school and ensuring that proper dosing guidelines and permission have been provided to the school. In addition, overuse needs to be avoided, limiting the NSAID (or any combination of nonprescription analgesics) to not more than 2-3 times per week. The limitation of any analgesic to not more than 3 headaches a week is necessary to prevent the transformation of the migraines into medication overuse headaches. If a patient has maximized the weekly allowance of analgesics, the patient’s next step is to only use hydrating fluids for the rest of the week as an abortive approach. If ibuprofen is not effective, naproxen sodium also may be tried in similar doses. Aspirin is also a reasonable option but is usually reserved for older children (older than age 15 yr). Use of other NSAIDs have yet to be studied in pediatric migraine. The goal of the primary acute medication should be headache relief within 1 hr with return to function in 10 of 10 headaches.

When a migraine is especially severe, NSAIDs alone may not be sufficient. In this case, a triptan may be considered. Multiple studies have demonstrated their effectiveness and tolerability. There are currently 2 triptans that are approved by the FDA for the treatment of episodic migraine in the pediatric population. Almotriptan is approved for the treatment of acute migraine in adolescents (ages 12-17 yr). Rizatriptan is approved for the treatment of migraine in children as young as age 6 yr. The combination of naproxen sodium and sumatriptan has been studied and may be effective in children. Controlled clinical trials demonstrate that intranasal sumatriptan is safe and effective in children older than age 8 yr with moderate to severe migraine. At present, pediatric studies showing the effectiveness of oral sumatriptan are lacking and there is insufficient evidence to support the use of subcutaneous sumatriptan in children. For most adolescents, dosing is the same as for adults; a reduction in dose is made for children weighing less than 40 kg. The triptans vary by rapidity of onset and biologic half-life. This is related to both their variable lipophilicity and dose. Clinically, 60-70% of patients respond to the first triptan tried, with 60-70% of the patients who did not respond to the first triptan responding to the next triptan. Therefore, in the patient who does not respond to the first triptan in the desired way (rapid reproducible response without relapse or side effects), it is worthwhile to try a different triptan. The most common side effects of the triptans are caused by their mechanism of action—tightness in the jaw, chest, and fingers as a result of vascular constriction and a subsequent feeling of grogginess and fatigue from the central serotonin effect. The vascular constriction symptoms can be alleviated through adequate fluid hydration during an attack.

The most effective way to administer abortive treatment is to use NSAIDs first in mild to severe cases, restricting their use to fewer than 2-3 attacks per week, and adding the triptan for moderate to severe, or attacks that have failed NSAID use, restricting to not more than 4-6 attacks per month. For an acute attack, the NSAIDs can be repeated once in 3-4 hr if needed for that specific attack, and the triptans can be repeated once in 2 hr if needed. It is important to consider the various formulations available and a discussion of these options should be made with pediatric patients and their parents, especially if a child is unable to swallow pills or take an oral dose because of nausea.

As vascular dilation is a common feature of migraine that may be responsive for some of the facial flushing followed by paresthesia and the lightheaded feeling accompanying the attacks, fluid hydration should be integrated into the acute treatment plan. For oral hydration this can include the sports drinks that combine electrolytes and sugar to provide the intravascular rehydration.

Antiemetics were used for acute treatment of the nausea and vomiting. Further study has identified that their unique mechanism of effectiveness in headache treatment is related to their antagonism of dopaminergic neurotransmission. Therefore, the antiemetics with the most robust dopamine antagonism (i.e., prochlorperazine and metoclopramide) have the best efficacy. These can be very effective for status migrainous or a migraine that is unresponsive to the NSAIDs and triptans. They require intravenous administration, as other forms of administration of these drugs are less effective than the NSAIDs or triptans. When combined with ketorolac and intravenous fluids in the emergency department or an acute infusion center, intravenous antiemetics can be very effective. When they are not effective, further inpatient treatment may be required using dicyclomamine (DHE) which will mean an admission to an inpatient unit for more aggressive therapy of an intractable attack.

**Emergency Department Treatments for Intractable Headaches**
When an acute migraine attack does not respond to an outpatient regimen and is disabling, other therapeutic approaches are available and may be necessary to prevent further increases in the frequency of headaches. These migraines fall into the classification of status migrainosus and need infusion therapy and admission to the emergency room department or to an inpatient unit.

Available specific treatments for migraine headache in an emergency room setting include the following: antidopaminergic medications such as prochlorperazine and metoclopramide; NSAIDs such as ketorolac and DHE; antiepileptic drugs such as sodium valproate; and triptans.

**Antidopaminergic Drugs: Prochlorperazine and Metoclopramide**. The use of these medications is not limited to controlling the nausea and vomiting often present during a migraine headache. Their potential pharmacologic effect may be a result of their dopaminergic antagonist action, which includes the antagonism of the dopaminergic property and the underlying pathologic process involving the dopaminergic system during a migraine attack. Prochlorperazine is very effective in aborting an attack in the emergency room when given intravenously with a bolus of IV fluid. Results show a 75% improvement with 50% headache freedom at 1 hr and 95% improvement with 60% headache freedom at 3 hr. Prochlorperazine may be more effective than metoclopramide. The average dose of metoclopramide use is 0.13-0.15 mg/kg with a maximum dose of 10 mg given intravenously over 15 min. The average dose of prochlorperazine is 0.15 mg/kg with a maximum dose of 10 mg. These medications are usually well tolerated, but extrapyramidal reactions are more frequent in children compared to the older population. An acute extrapyramidal reaction can be controlled in the emergency room with 25-50 mg of diphenhydramine given IV.

**Nonsteroidal Antiinflammatory Drugs: Ketorolac**. It is known that an aseptic inflammation occurs in the central nervous system as a result of the effect of multiple reactive peptides in patients with migraines. Ketorolac is often used in the emergency department as monotherapy for a migraine attack or in combination with other drugs. In monotherapy, the response to ketorolac is 55.2% improvement. When combined to prochlorperazine, the response rate jumps to 93%.
Antiepileptic Drugs: Sodium Valproate. Antiepileptic drugs have been used as prophylactic treatment for migraine headache for years with adequate double-blinded, controlled studies on their efficacy in adults. The mechanism in which sodium valproate acutely aborts migraine headaches is not well understood. Sodium valproate is given as a bolus of 15-20 mg/kg push (over 10 min). This intravenous load is followed by an oral dose (15-20 mg/day) in the 4 hr after the injection. Patients may benefit from a short-term preventive treatment with an extended release form after discharge from the emergency room. Sodium valproate is usually well tolerated. Patients should be receiving a fluid load during the procedure to prevent a possible hypotensive episode.

Triptans. Subcutaneous sumatriptan (0.06 mg/kg) has an overall efficacy of 72% at 30 min and 78% at 2 hr, with a recurrence rate of 6%. Because children tend to have a shorter duration of headache, a recurrence rate of 6% would seem appropriate for this population. DHE, if recommended for the recurrences, should not be given in the 24 hr after triptan use. Triptans are contraindicated in patients treated with monoamine oxidase inhibitors. Triptans may potentially produce a serotonin syndrome in patients taking a serotonin syndrome reuptake inhibitor. Both triptans and ergotamine are contraindicated in hemiplegic migraines.

Dihydroergotamine. DHE is an old migraine medication used as a vasoconstrictor to abort the vascular phase of migraine headache. The effectiveness is discussed in detail in the section “Inpatient Management of Intractable Migraine and Status Migrinosus” below. One dose of DHE can be effective for abortive treatment in the emergency department. Emergency room treatment of migraine shows a recurrence rate of 29% at 48-72 hr, with 6% who need more aggressive therapy in an inpatient unit.

Inpatient Management of Intractable Migraine and Status Migrinosus

Six percent to 7% of patients fail acute treatment in the emergency department. These patients are usually admitted for a 3-5 day stay and receive extensive parenteral treatment. A child should be admitted to the hospital for a primary headache when the child is in status migrainous, has an exacerbation of a chronic severe headache, or is in an analgesic rebound headache. The goal of inpatient treatment is to control a disabling headache that has been unresponsive to other abortive therapy and is disabling to the child. Treatment protocols include the use of DHE, antimetics, sodium valproate and other drugs.

Dihydroergotamine. Ergots are one of the oldest treatments for migraine headache. DHE is a parenteral form used for acute exacerbations. Its effect is because of the 5HT1A-1B-1D-1F receptor agonist for migraine headache. DHE is a parenteral form used for acute exacerbation of acute emergency department. Emergency room treatment of migraine shows a patient’s history and comorbid problems. A protocol is 15

the fifth dose and can reach its maximum effects after the 10th dose. Treatment and 77% headache freedom. Response starts being noticeable by headache ceases, an extra dose is given in an attempt to prevent recurrence every 8 hr until headache freedom. When headache ceases, an extra dose is given in an attempt to prevent recurrence after discharge. The response to this protocol is a 97% improvement and 77% headache freedom. Response starts being noticeable by the fifth dose and can reach its maximum effects after the 10th dose. Side effects of DHE include nausea, vomiting, abdominal discomfort, flushed face, increased blood pressure. The maximum dose used in this protocol is 15 mg total of DHE. During the hospital admission the patient is usually started on migraine prophylaxis depending on the patient’s history and comorbid problems.

Sodium Valproate. Sodium valproate is used when DHE is contraindicated or has been ineffective. One adult study recommends the use of valproate sodium as follows: Bolus with 15 mg/kg (maximum of 1,000 mg), followed by 5 mg/kg every 8 hr until headache freedom or up to a maximum of 10 doses. Always give an extra dose after headache ceases. This protocol was studied in adults with chronic daily headaches and showed an 80% improvement. It is well tolerated and is useful in children when DHE is ineffective, contraindicated, or not tolerated.

Preventive Therapy

When the headaches are frequent (more than 1 headache/wk) or there are more than 1 disabling headache a month (missing school, home, or social activities, or a PedMIDAS score higher than 20), preventive or prophylactic therapy is warranted. The goal of this therapy should be to reduce frequency (1-2 headaches or fewer per month) and disability (PedMIDAS score <10). Prophylactic agents should be given for at least 4-6 mo at an adequate dose and then weaned over several weeks. Evidence in adult studies has begun to demonstrate that persistent frequent headaches foreshadow an increased risk of progression with decreased responsiveness and increased risk of refractoriness in the future. It is unclear whether this also occurs in children and/or adolescents and whether early treatment of headache in childhood prevents development of refractory headache in adulthood.

Multiple preventive medications have been utilized for migraine prophylaxis in children. When analyzed as part of a practice parameter, only 1 medication, flunarizine (a calcium channel blocking agent), demonstrated a level of effectiveness viewed as substantial; it is not available in the United States. Flunarizine is typically dosed at 5 mg orally daily and increased after 1 mo to 10 mg orally daily, with a month off of the drug every 4-6 mo.

The most commonly used preventive therapy for headache and migraine is amitriptyline. Typically, a dose of 1 mg/kg daily at dinner or in the evening is effective. However, this dose needs to be reached slowly (i.e., over weeks: with an increase every 2 wk until goal is reached) to minimize side effects and improve tolerability. The most common side effects are sleepiness and those related to amitriptyline's anticholinergic activity. Weight gain has been observed in adults using amitriptyline but is a less frequent occurrence in children. Amitriptyline does have the potential to exacerbate prolonged QT syndrome, so it should be avoided in patients with this diagnosis and looked for in patients on the drug who complain of rapid or irregular heart rate.

Antiepileptic medications are also used for migraine prophylaxis, with topiramate, valproic acid, and levetiracetam having been demonstrated to be effective in adults. There are limited studies in children for migraine prevention, but all of these medications have been assessed for safety and tolerability in children with epilepsy.

Topiramate has become widely used for migraine prophylaxis in adults. Topiramate was also demonstrated to be effective in an adolescent study. This study demonstrated that a 25 mg dose twice a day was equivalent to placebo, whereas a 50 mg dose twice a day was superior. Thus it appears that the adult dosing schedule is also effective in adolescents with an effective dosage range or 50 mg twice a day to 100 mg twice a day. This dose needs to be reached slowly to minimize the cognitive slowing associated with topiramate use. Additional side effects include weight loss, paresthesia, kidney stones, lowered bicarbonate levels, decreased sweating, and rarely glaucoma and changes in serum transaminases. In addition, in adolescent girls taking birth control pills, the lowering of the effectiveness of the birth control by topiramate needs to be discussed.

Valproic acid has long been used for epilepsy in children and has been demonstrated to be effective in migraine prophylaxis in adults. The effective dose in children appears to be 10 mg/kg orally twice a day. Side effects of weight gain, ovarian cysts, and changes in serum transaminases and platelet counts need to be monitored. Other anti-epileptics, including lamotrigine, levetiracetam, zonisamide, gabapentin, and pregabalin, are also used for migraine prevention.

β-Blockers have long been used for migraine prevention. The studies on β-blockers have a mixed response pattern with variability both between β-blockers and between patients with a given β-blocker. Propranolol is the best studied for pediatric migraine prevention with unequivocally positive results. The contraindication for use of
propranolol in children with asthma or allergic disorders or diabetes and the increased incidence of depression in adolescents using propranolol limit its use somewhat. It may be very effective for a mixed subtype of migraine (basilar-type migraine with postural orthostatic tachycardia syndrome). This syndrome has been reported to be responsive to propranolol. α-Blockers and calcium channel blockers, aside from flunarizine, also have been used in pediatric migraine; their effectiveness, however, remains unclear.

In very young children, cyproheptadine may be effective in prevention of migraine or the related variants. Young children tend to tolerate the increased appetite induced by the cyproheptadine and tend not to be subject to the lethargy seen in older children and adults; the weight gain is limiting once children start to enter puberty. Typical dosing is 0.1-0.2 mg/kg orally twice a day.

Nutraceuticals have become increasingly popular over the past few years, especially among families who prefer a more “natural” approach to headache treatment. Despite studies showing success of these therapies in adults, few studies have shown effectiveness in pediatric headaches. Riboflavin (vitamin B2), at doses ranging from 25-400 mg, is the most widely studied with good results. Side effects are minimal and include bright yellow urine, diarrhea, and polyuria. Coenzyme Q10 supplementation may be effective in reducing migraine frequency at doses of 1-2 mg/kg/day. Butterbur is also effective in reducing headaches with minimal side effects, including burping. Use in children has been limited to avoid the potential toxicity of butterbur containing pyrrolizidine alkaloids, which are naturally contained and are a known carcinogen and toxic to the liver.

OnabotulinumtoxinA is the first medication FDA-approved for chronic migraine in adults. There are studies in children indicating its effectiveness; use in children is considered off-label. The limited available studies revealed the following: Average dose used was 188.5 units ± 32 units with a minimum dose of 75 units and maximum of 200 units. The average age of patients receiving the treatment was 16.8 ± 2.0 yr (minimum: 11; maximum: 21 yr old). OnabotulinumtoxinA injections improved disability scores (PedMIDAS) and headache frequency in pediatric chronic daily headache patients and chronic migraine in this age group. OnabotulinumtoxinA not only had a positive effect on the disability scoring for these young patients with headache, but was also able to transform the headaches from chronic daily to intermittent headache in more than 50% of the patients.

### Biobehavioral Therapy

Biobehavioral evaluation and therapy is essential for effective migraine management. This includes identification of behavioral barriers to treatment, like a child's shyness or limitation in notifying a teacher of the start of a migraine or a teacher's unwillingness to accept the need for treatment. Additional barriers include a lack of recognition of the significance of their headache problem and reverting to “bad habits” once the headaches have responded to treatment. Adherence is equally important for acute and preventive treatment. The need to have a sustained response for long enough to prevent relapse (i.e., to stay on preventive medication) is often difficult when the child starts to feel better. Establishing a defined treatment goal (1-2 or fewer headaches per month for 4-6 mo) helps with acceptance.

As many of the potential triggers for frequent migraines (skipping meals, dehydration, decreased or altered sleep) are related to a child's daily routine, a discussion of healthy habits is a component of biobehavioral therapy. This should include adequate fluid intake without caffeine, regular exercise, not skipping meals and making healthy food choices, and adequate (8-9 hr) sleep on a regular basis. Sleep is often difficult in adolescents, as middle and high schools often have very early start times, and the adolescent's sleep architecture features a shift to later sleep onset and waking. This has been one of the explanations for worsening headaches during the school year in general and at the beginning of the school year and week.

Biofeedback-assisted relaxation and cognitive behavioral therapy (usually in combination with amitriptyline) are effective for both acute and preventive therapy and may be incorporated into this multiple treatment strategy. This provides the child with a degree of self-control over the headaches and may further help the child cope with frequent headaches.

### 595.2 Secondary Headaches

Andrew D. Hershey, Marielle A. Kabbouche, and Hope L. O'Brien

Headaches can be a common symptom of other underlying illnesses. In recognition of this, the ICHD-3 beta has classified the potential secondary headaches (see Table 595-1). The key to the diagnosis of a secondary headache is to recognize the underlying cause and demonstrate a direct cause and effect. Until this has been demonstrated the diagnosis is speculative. This is especially true when the suspected etiology is common.

Common causes or suspected causes of secondary headaches in children include the sequela of head trauma and sinusitis. Posttraumatic headaches sometimes occur in children who have not had a prior history of headaches and are temporarily related to the initiating head injury. Frequently, though, these children have a family history of migraine or its equivalent. The head injury may be minor or major and the subsequent headache may be acute (resolves within 3 mo, most typically within 10 days) or chronic (longer than 15 days per month for more than 3 mo). Bed rest appears to be the most effective treatment for acute posttraumatic headache; magnesium supplementation and migraine prophylaxis may also be effective. When a child has a history of episodic headaches, the head trauma or the overuse of daily medications may lead to status migrainosus or chronic migraine and the diagnosis may be difficult to sort out.

Sinus headache is the most overdiagnosed form of recurrent headaches. Although no studies have evaluated the frequency of misdiagnosis of an underlying migraine as a sinus headache in children, in adults, it has been found that up to 90% of adults diagnosed as having a sinus headache by either themselves or their physician appear to have migraine. When headaches are recurrent and respond within hours to analgesics, migraine should be considered first. In the absence of purulent nasal discharge, fever, or chronic cough, the diagnosis of sinus headache should not be made.

Medication overuse headaches frequently complicate primary and secondary headaches. A medication overuse headache is defined as a headache present for more than 15 days/mo for longer than 3 mo and intake of a simple analgesic on more than 15 days/mo and/or prescription medications including triptans or combination medications on more than 10 days/mo. Some of the signs that should raise suspicion of medication overuse are the increasing use of analgesics (nonprescription or prescription) with either decreased effectiveness or frequently wearing off (i.e., analgesic rebound). This can be worsened by using ineffective medications and underdosing or misdiagnosing the headache. Patients should be cautioned against the frequent use of antimigraine medications, including combination analgesics or triptans.

Serious causes of secondary headaches are likely to be related to increased intracranial pressure. This can be caused by a mass (tumor, vascular malformation, cystic structure) or an intrinsic increase in pressure (idiopathic intracranial hypertension also known as pseudo-tumor cerebi). In the former case, the headache is caused by the mass effect and local pressure on the dura; in the latter case, the headache is caused by diffuse pressure on the dura. The etiology of idiopathic intracranial hypertension may be the intake of excessive amounts of fat-soluble compounds (e.g., vitamin A, retinoic acid, and minocycline), hormonal changes (increased incidence in females) or blockage of venous drainage (as with inflammation of the transverse venous sinus from mastoiditis). When increased pressure is suspected, either by historical suspicion or the presence of papilledema, an MRI with magnetic resonance angiography and magnetic resonance venography should be performed, followed by a lumbar puncture if no mass or
Evaluation of patients with suspected TTHs requires a detailed headache history and complete general and neurologic examination. This is to establish the diagnosis and ensure exclusion of secondary etiologies. When secondary headaches are suspected, further, directed evaluation is indicated.

Treatment of TTHs can require acute therapy to stop attacks, preventive therapy when frequent or chronic, and behavioral therapy. It is often suspected that there may be underlying psychologic stressors (hence the misnomer as a “stress” headache), but this is often difficult to identify in children, and although it may be suspected by the parents, it cannot be confirmed in the child. Studies of and conclusive evidence to guide the treatment of TTH in children are lacking, but the same general principles and medications used in migraine can be applied to children with TTHs (see Chapter 595.1). Oftentimes, simple analgesics (ibuprofen or acetaminophen) can be effective for acute treatment. Flupirtine is a nonopioid analgesic that has been approved in Europe for the treatment of TTH in children as young as age 6 yr, but is not available in the United States. Amitriptyline has the most evidence of effective prevention of TTH; biobehavioral intervention, including biofeedback-assisted relaxation training and coping skills, can be useful as well.

Bibliography is available at Expert Consult.

### 595.3 Tension-Type Headaches

Andrew D. Hershey, Marielle A. Kabbouche, and Hope L. O’Brien

Tension-type headaches (TTHs) may be very common in children and adolescents with prevalence in some studies shown as high as 48%, with those having a combination of migraine and TTH around 20%. Because of their mild to moderate nature, relative lack of associated symptoms and lower degree of associated disability they are often ignored or have a minimal impact. The ICHD-3 beta subclassifies TTHs as infrequent (<12 times/yr) (Table 595-9), frequent (1-15 times/mo), and chronic (>15 headaches/mo). They can further be separated into headaches with or without pericranial muscle tenderness. The classification of TTH can be likened to the opposite of migraine. Whereas migraines are typically moderate to severe, are focal in location, are worsened by physical activity or limit physical activity, and have a throbbing quality, TTH are mild to moderate in severity, are diffuse in location, are not affected by activity (although the patient may not feel like being active), and are nonthrobbering (often described as a constant pressure). TTH is much less frequently associated with nausea, photophobia, or phonophobia and is never associated with more than 1 of these at a time or with vomiting. TTH must be recurrent, but at least 10 headaches are required and the duration can be 30 min to 7 days. Secondary headaches with other underlying etiologies must be ruled out.

The neurocutaneous syndromes include a heterogeneous group of disorders characterized by abnormalities of both the integument and central nervous system. Many of the disorders are familial and believed to arise from a defect in differentiation of the primitive ectoderm. Disorders classified as neurocutaneous syndromes include neurofibromatosis, tuberous sclerosis, Sturge-Weber syndrome, von Hippel-Lindau disease, PHACE (posterior fossa malformations, hemangiomas, arterial anomalies, coarctation of aorta, cardiac defects, eye abnormalities) syndrome, ataxia telangiectasia, linear nevus syndrome, hypomelanosis of Ito, and incontinentia pigmenti.

### 596.1 Neurofibromatosis

Mustafa Sahin

Neurofibromatoses are autosomal dominant disorders that cause tumors to grow on nerves and result in other abnormalities such as skin changes and bone deformities. It was believed that there were 2 types of neurofibromatosis (type 1 and type 2), but it is recognized that they are clinically and genetically distinct diseases and should be considered separate entities: neurofibromatosis type 1 (NF-1) and neurofibromatosis type 2 (NF-2).

**CLINICAL MANIFESTATIONS AND DIAGNOSIS**

NF-1 is the most prevalent type, with an incidence of 1 in 3,000 live births, and is caused by dominant loss-of-function mutations in the NF-1 gene. The disease is clinically diagnosed when any 2 of the following 7 features are present: (1) six or more café-au-lait macules larger than 5 mm in greatest diameter in prepubertal individuals and larger than 15 mm in greatest diameter in postpubertal individuals (Fig. 596-1). Café-au-lait spots are the hallmark of neurofibromatosis.
Neurocutaneous Syndromes

NF-1 but are not a characteristic of NF-2. The prevalence of Lisch nodules increases with age, from only 5% of children younger than 3 yr of age, to 42% among children 3-4 yr of age, and virtually 100% of adults older than 21 yr of age. (4) Two or more neurofibromas or 1 plexiform neurofibroma. Neurofibromas typically involve the skin, but they may be situated along peripheral nerves and blood vessels and within viscera including the gastrointestinal tract. These lesions appear characteristically during adolescence or pregnancy, suggesting a hormonal influence. They are usually small, rubbery lesions with a slight purplish discoloration of the overlying skin. Plexiform neurofibromas are usually evident at birth and result from diffuse thickening of nerve trunks that are frequently located in the orbital or temporal region of the face. The skin overlying a plexiform neurofibroma may be hyperpigmented to a greater degree than a café-au-lait macule. Plexiform

Table 596-1 Diseases Associated with Multiple Café-Au-Lait Spots

Figure 596-1 A and B, Multiple café-au-lait spots over the back. Note the dermal neurofibromas below the right scapula and right side of the lower back. (From Hersh JH, Committee on Genetics: Health supervision for children with neurofibromatosis, Pediatrics 121:633–642, 2008, Fig. 1.)

and are present in almost 100% of patients. They are present at birth but increase in size, number, and pigmentation, especially during the 1st few yr of life. The spots are scattered over the body surface, with predilection for the trunk and extremities but sparing the face. (2) Axillary or inguinal freckling consisting of multiple hyperpigmented areas 2-3 mm in diameter. Skinfold freckling usually appears between 3 and 5 yr of age. The frequency of axillary and inguinal freckling is reported to be >80% by 6 yr of age. Café-au-lait macules are not specific for NF-1; they may be seen in Noonan syndrome, constitutional mismatch repair deficiency syndrome, Legius syndrome, Peutz-Jeghers syndrome, Carney complex, and those diseases listed in Table 596-1.

(3) Two or more iris Lisch nodules. Lisch nodules are hamartomas located within the iris and are best identified by a slit-lamp examination (Fig. 596-2). They are present in more than 74% of patients with NF-1 but are not a characteristic of NF-2. The prevalence of Lisch nodules increases with age, from only 5% of children younger than 3 yr of age, to 42% among children 3-4 yr of age, and virtually 100% of adults older than 21 yr of age. (4) Two or more neurofibromas or 1 plexiform neurofibroma. Neurofibromas typically involve the skin, but they may be situated along peripheral nerves and blood vessels and within viscera including the gastrointestinal tract. These lesions appear characteristically during adolescence or pregnancy, suggesting a hormonal influence. They are usually small, rubbery lesions with a slight purplish discoloration of the overlying skin. Plexiform neurofibromas are usually evident at birth and result from diffuse thickening of nerve trunks that are frequently located in the orbital or temporal region of the face. The skin overlying a plexiform neurofibroma may be hyperpigmented to a greater degree than a café-au-lait macule. Plexiform
The Nervous System

Thalamus, internal capsule, and cerebellum (Fig. 596-4). These signals, “unidentified bright objects,” tend to disappear with age; most have disappeared by 30 yr of age. It is unclear what the unidentified bright objects represent pathologically, and there is disagreement as to the relationship between the presence and number of unidentified bright objects and the occurrence of learning disabilities, attention-deficit disorders, behavioral and psychosocial problems, and abnormalities of speech among affected children. Therefore, imaging studies such as brain MRIs should be reserved for patients with clinical symptoms only.

One of the most common complications is learning disability affecting approximately 30% of children with NF-1. Seizures are observed in approximately 8% of NF-1 patients. The cerebral vessels may develop aneurysms or stenosis resulting in moyamoya syndrome (see Chapter 601). Neurologic sequelae of these vascular abnormalities include transient cerebrovascular ischemic attacks, hemiparesis, and cognitive defects. Precocious puberty may become evident in the presence or absence of lesions of the optic pathway tumors. Malignant neoplasms are also a significant problem in patients with NF-1, affecting approximately 3% of patients. A neurofibroma occasionally differentiates into a malignant peripheral nerve sheath tumor. The incidence of pheochromocytoma, rhabdomyosarcoma, leukemia, and Wilms tumor is higher than in the general population. Scoliosis is a common complication found in approximately 10% of the patients. Patients with NF-1 are at risk for hypertension, which may result from renal vascular stenosis or a pheochromocytoma.

Management

Because of the diverse and unpredictable complications associated with NF-1, close multidisciplinary follow-up is necessary. Patients with NF-1 should have regular clinical assessments at least yearly, focusing on the history and examination on the potential problems for which they are at increased risk. These assessments include yearly ophthalmologic examinations. When they progress, visual symptoms occur because the tumors enlarge and put pressure on the optic nerves and chiasm resulting in impaired visual acuity and visual fields. Extension into the hypothalamus can lead to endocrine deficiencies or failure to thrive. The MRI findings of an optic glioma include diffuse thickening, localized enlargement, or a distinct focal mass originating from the optic nerve or chiasm (Fig. 596-3). (7) A 1st-degree relative with NF-1 whose diagnosis was based on the aforementioned criteria.

Children with NF-1 are susceptible to neurologic complications. MRI studies of selected children have shown abnormal hyperintense T2-weighted signals in the optic tracts, brainstem, globus pallidus, thalamus, internal capsule, and cerebellum (Fig. 596-4). These signals, “unidentified bright objects,” tend to disappear with age; most have disappeared by 30 yr of age. It is unclear what the unidentified bright objects represent pathologically, and there is disagreement as to the relationship between the presence and number of unidentified bright objects and the occurrence of learning disabilities, attention-deficit disorders, behavioral and psychosocial problems, and abnormalities of speech among affected children. Therefore, imaging studies such as brain MRIs should be reserved for patients with clinical symptoms only.

One of the most common complications is learning disability affecting approximately 30% of children with NF-1. Seizures are observed in approximately 8% of NF-1 patients. The cerebral vessels may develop aneurysms or stenosis resulting in moyamoya syndrome (see Chapter 601). Neurologic sequelae of these vascular abnormalities include transient cerebrovascular ischemic attacks, hemiparesis, and cognitive defects. Precocious puberty may become evident in the presence or absence of lesions of the optic pathway tumors. Malignant neoplasms are also a significant problem in patients with NF-1, affecting approximately 3% of patients. A neurofibroma occasionally differentiates into a malignant peripheral nerve sheath tumor. The incidence of pheochromocytoma, rhabdomyosarcoma, leukemia, and Wilms tumor is higher than in the general population. Scoliosis is a common complication found in approximately 10% of the patients. Patients with NF-1 are at risk for hypertension, which may result from renal vascular stenosis or a pheochromocytoma.

Management

Because of the diverse and unpredictable complications associated with NF-1, close multidisciplinary follow-up is necessary. Patients with NF-1 should have regular clinical assessments at least yearly, focusing on the history and examination on the potential problems for which they are at increased risk. These assessments include yearly ophthalmologic examination, neurologic assessment, blood pressure monitoring, and scoliosis evaluation. Neuropsychologic and educational testing should be considered as needed. The National Institutes of Health (NIH) Consensus Development Conference has advised against routine imaging studies of the brain and optic tracts because treatment in these
asymptomatic NF-1 children is rarely required. However, all symptomatic cases (i.e., those with visual disturbance, proptosis, increased intracranial pressure) must be studied without delay.

**GENETIC COUNSELING**

Although NF-1 is an autosomal dominant disorder, more than half the cases are sporadic, representing de novo mutations. The NF-1 gene on chromosome region 17q11.2 encodes for a protein also known as neurofibromin. Neurofibromin acts as an inhibitor of the oncogene Ras. The diagnosis of NF-1 is based on the clinical features. However, molecular testing for the NF-1 gene mutations is available and can be useful in a number of cases. Some scenarios in which genetic testing is helpful include for patients who meet only 1 of the criteria for clinical diagnosis, those with unusually severe disease, and those seeking prenatal/preimplantation diagnosis. 

NF-2 is a rarer condition, with an incidence of 1 in 25,000 births, and may be diagnosed when 1 of the following 4 features is present: (1) bilateral vestibular schwannomas; (2) a parent, sibling, or child with NF-2 and either unilateral vestibular schwannoma or any 2 of the following: meningioma, schwannoma, glioma, neurofibroma, posterior subcapsular lenticular opacities; (3) unilateral vestibular schwannoma and any 2 of the following: meningioma, schwannoma, glioma, neurofibroma, posterior subcapsular lenticular opacities; or (4) multiple meningiomas (2 or more) and unilateral vestibular schwannoma or any 2 of the following: schwannoma, glioma, neurofibroma, cataract. Symptoms of tinnitus, hearing loss, facial weakness, headache, or unsteadiness may appear during childhood, although signs of a cerebellopontine angle mass are more commonly present in the 2nd and 3rd decades of life. Although café-au-lait macules and skin neurofibromas are classic findings in NF-1, they are much less common in NF-2. Posterior subcapsular lens opacities are identified in approximately 50% of patients with NF-2. The NF-2 gene (which codes for a protein known as merlin or schwannomin) is located on chromosome 22q11.1. Table 596-2 notes the frequency of lesions in NF-2.

**Legius syndrome** (caused by SPRED1 mutations) resembles a mild form of NF-1. Patients with Legius syndrome present with multiple café-au-lait macules and macrocephaly, with and without skinfold freckling. However, other typical features of NF-1, such as Lisch nodules, neurofibromas, optic nerve gliomas, and malignant peripheral nerve sheath tumors, are not seen with SPRED1 mutations.

**596.2 Tuberous Sclerosis**

Mustafa Sahin

Tuberous sclerosis complex (TSC) is inherited in an autosomal dominant manner with variable expression and a prevalence of 1 in 6,000 newborns. Spontaneous genetic mutations occur in 65% of the cases. Molecular genetic studies have identified 2 foci for TSC: the TSC1 gene is located on chromosome 9q34, and the TSC2 gene is on chromosome 16p13. The TSC1 gene encodes a protein called hamartin, while the TSC2 gene encodes the protein tuberin. Within a cell, these 2 proteins bind to one another and work together. Consequently, a mutation in either the TSC1 gene or the TSC2 gene results in a similar disease in patients. The TSC1 and TSC2 genes are tumor-suppressor genes. The loss of either tuberin or hamartin protein results in the formation of numerous benign tumors (hamartomas). Tuberin and hamartin are involved in a key pathway in the cell that regulates protein synthesis and cell size. One of the ways cells regulate their growth is by controlling the rate of protein synthesis. A protein called mTOR (mammalian target of rapamycin) was identified as one of the master regulators of cell growth. mTOR, in turn, is controlled by rhabdomyosarcoma guanosine triphosphatase. When rhabdomyosarcoma is activated, the protein synthesis machinery is turned on, most likely via mTOR, and the cell grows in size. Of interest in TSC, rhabdomyosarcoma is activated by the protein complex formed by hamartin and tuberin.

TSC is an extremely heterogeneous disease with a wide clinical spectrum varying from severe intellectual disability and intractable epilepsy to normal intelligence and a lack of seizures; this variation is often seen within the same family, thus with individuals carrying the same mutation. The disease affects many organ systems other than the skin and brain, including the heart, kidney, eyes, lungs, and bone (Fig. 596-5).

**CLINICAL MANIFESTATIONS AND DIAGNOSIS**

Definite TSC is diagnosed when at least 2 major or one major plus 2 minor features are present (Tables 596-3 and 596-4 list the major and minor features). The hallmark of TSC is the involvement of the central nervous system. Retinal lesions consist of two types: hamartomas (elevated mulberry lesions or plaque-like lesions; Fig. 596-6) and white depigmented patches (similar to the hypopigmented skin lesions). The characteristic brain lesion is a cortical tuber (Fig. 596-7). Brain MRI is the best way of identifying cortical tubers, which can form before birth.

Subependymal nodules are lesions found along the wall of the lateral ventricles where they undergo calcification and project into the ventricular cavity, producing a candle-like appearance. These lesions do not cause any problems; however, in 5-10% of cases, these benign lesions can grow into subependymal giant cell astrocytomas (SEGAs). These tumors can grow and block the circulation of cerebrospinal fluid around the brain and cause hydrocephalus, which requires immediate neurosurgical intervention. Thus, it is recommended that all asymptomatic TSC patients undergo brain MRI every 1-3 yr to monitor for new occurrence of SEGAs. Patients with large or growing SEGAs, or with SEGAs causing ventricular enlargement but yet are still asymptomatic, should undergo MRI scans more frequently and the patients and their families should be educated regarding the potential of new symptoms due to increased intracranial pressure. Surgical resection should be performed for acutely symptomatic SEGAs. For growing but otherwise asymptomatic SEGAs, either surgical resection or medical treatment with an mTOR inhibitor may be used. Presymptomatic treatment with everolimus is effective in slowing the growth or even reducing the size of SEGAs. Everolimus is also effective in treating refractory seizures and reducing the volume of renal angiomyolipomas and lymphangiomyomatosis as well as facial angiofibromas.

The most common neurologic manifestations of TSC consist of epilepsy, cognitive impairment, and autism spectrum disorders. TSC may present during infancy with infantile spasms and a hypsarrhythmic electroencephalogram pattern. However, it is important to remember...
Bibliography
that you can have infantile spasms without hypsarrhythmia in TSC patients. The seizures may be difficult to control and, at a later age, they may develop into myoclonic epilepsy (see Chapter 593). Vigabatrin is the first-line therapy for infantile spasms. ACTH can be used if treatment with vigabatrin fails. Anticonvulsant therapy of other seizure types in TSC should generally follow that of other epilepsies, and epilepsy surgery should be considered for medically refractory TSC patients.

**SKIN LESIONS**

More than 90% of patients show the typical hypomelanotic macules that have been likened to an ash leaf on the trunk and extremities. Visualization of the hypomelanotic macule is enhanced by the use of a Wood ultraviolet lamp (see Chapter 653). To count as a major feature, at least three hypomelanotic macules must be present (see Fig. 596-5). Facial angiofibromas develop between 4 and 6 yr of age; they appear as tiny red nodules over the nose and cheeks and are sometimes confused with acne (see Fig. 596-5). Later, they enlarge, coalesce, and assume a fleshy appearance. A shagreen patch is also characteristic of TSC and consists of a roughened, raised lesion with an orange-peel consistency located primarily in the lumbosacral region (see Fig. 596-5). During adolescence or later, small fibromas or nodules

Figure 596-6 A mulberry lesion involving the superior part of the optic nerve in a patient with tuberous sclerosis. (From Yanoff M, Sassani JW: Ocular pathology, ed 7, Philadelphia, 2015, WB Saunders, Fig. 2-7.)
The current recommendation is to follow the angiomyolipoma by yearly imaging, and when the size of the lesion reaches more than 4 cm, to use transcatheter tumor embolization for treatment. Single or multiple renal cysts are also commonly present in TSC. Lymphangioleiomyomatosis is the classical pulmonary lesion in TSC and only affects women after the age of 20 yr.

Diagnosis of TSC relies on a high index of suspicion when assessing a child with infantile spasms. A careful evaluation for the typical skin and retinal lesions should be completed in all patients with a seizure disorder or autism spectrum disorder. Brain MRI confirms the diagnosis in most cases. Genetic testing for TSC1 and TSC2 mutations is available and may be considered when the individual patient does not meet all the clinical criteria. Prenatal testing may be offered when a known TSC mutation exists in that family.

**MANAGEMENT**

As for routine follow-up of individuals with TSC, the following are recommended in addition to physical examination: brain MRI every 1-3 yr, renal imaging (US, CT or MRI) every 1-3 yr and neurodevelopmental testing at the time of beginning 1st grade. Based on the complications of the disease, additional follow-up testing may be required for each individual. Symptoms and signs of increased intracranial pressure suggest obstruction of the foramen of Monro by a SEGA and warrant immediate investigation and surgical intervention.

**Sturge-Weber Syndrome**

**Mustafa Sahin**

Sturge-Weber syndrome (SWS) is a sporadic vascular disorder and consists of a constellation of symptoms and signs including a facial capillary malformation (port-wine stain), abnormal blood vessels of the brain (leptomeningeal angiomia) and abnormal blood vessels of the eye leading to glaucoma. Patients present with seizures, hemiparesis, stroke-like episodes, headaches, and developmental delay. Approximately 1 in 50,000 live births are affected with SWS.
Bibliography

ETIOLOGY
The sporadic incidence and focal nature of SWS suggests the presence of somatic mutations. Whole-genome sequencing from affected and unaffected skin of 3 patients with SWS identified a single-nucleotide variant (c.548G→A, p.Arg183Gln) in the GNAQ gene. This mutation has been confirmed in samples of affected tissue from 88% of a larger cohort of SWS patients as well as 92% of the participants with apparently nonsyndromic port-wine stains. Brain tissue from SWS patients also demonstrated the same change in the GNAQ gene. These results strongly suggest that SWS occurs as a result of mosaic mutations in GNAQ.

The condition is thought to result from anomalous development of the embryonic vascular bed in the early stages of facial and cerebral development. There are hypotheses about aberrant sympathetic innervation, increased vascular growth factors and defects in extracellular matrix, but these remain to be tested. Low flow angiomatosis of the leptomeninges appears to result in a chronic hypoxic state leading to cortical atrophy and calcifications.

CLINICAL MANIFESTATIONS
The facial port-wine stain is present at birth, tends to be unilateral, and always involves the upper face and eyelid, in a distribution consistent with the ophthalmic division of the trigeminal nerve (Fig. 596-9). The capillary malformation may also be evident over the lower face, trunk, and in the mucosa of the mouth and pharynx. It is important to note that not all children with facial port-wine stain have SWS even though the genetic defect appears to be the same. In fact, the overall incidence of SWS has been reported to be 8-33% in those with a port-wine stain. Buphthalmos and glaucoma of the ipsilateral eye are common complications. The incidence of epilepsy in patients with SWS is 75-90%, and seizures develop in most patients in the 1st yr of life. They are typically focal tonic-clonic and contralateral to the side of the facial capillary malformation. The seizures may become refractory to anticonvulsants and are associated with a slowly progressive hemiparesis in many cases. Transient stroke-like episodes or visual defects persisting for several days and unrelated to seizure activity are common and probably result from thrombosis of cortical veins in the affected region. Although neurodevelopment appears to be normal in the 1st yr of life, intellectual disability or severe learning disabilities are present in at least 50% in later childhood, probably the result of intractable epilepsy and increasing cerebral atrophy.

DIAGNOSIS
MRI with contrast is the imaging modality of choice for demonstrating the leptomeningeal angioma in SWS (Fig. 596-10). White matter abnormalities are common and are thought to be a result of chronic hypoxia. Often, atrophy is noted ipsilateral to the leptomeningeal angiomatosis. Calcifications can be seen best with a head CT (Fig. 596-11).

Figure 596-9 Port-wine stain involving both V1 and V2 dermatomes. (Courtesy of Dr. Anne W. Lucky, Cincinnati Children’s Hospital.)

Figure 596-10 Gadolinium-enhanced axial T1 fluid-attenuated inversion recovery (FLAIR) images of a 15 mo old with Sturge-Weber syndrome shows leptomeningeal enhancement in left hemisphere.

Figure 596-11 CT scan of a patient with Sturge-Weber syndrome showing unilateral calcification and underlying atrophy of a cerebral hemisphere.
Incontinentia
Neurocutaneous
Von

1. Type I—Both facial and leptomeningeal angiomas; may have
glaucoma
2. Type II—Facial angioma alone (no central nervous system
involvement); may have glaucoma
3. Type III—Isolated leptomeningeal angiomas; usually no
glaucoma

MANAGEMENT
Management of SWS is symptomatic and multidisciplinary but not
well studied by prospective studies. It is aimed at seizure control, treat-
ment of headaches, and prevention of stroke-like episodes, as well as
monitoring of glaucoma and laser therapy for the cutaneous capillary
malformations. Seizures beginning in infancy are not always associated
with a poor neurodevelopmental outcome. For patients with well-
controlled seizures and normal or near-normal development, manage-
ment consists of anticonvulsants and surveillance for complications
including glaucoma, buphthalmos, and behavioral abnormalities. If the
seizures are refractory to anticonvulsant therapy, especially in infancy
and the 1st 1-2 yr, and arise from primarily 1 hemisphere, most medical
centers advise a hemispherectomy. Because of the risk of glaucoma,
regular measurement of intraocular pressure is indicated. The facial
port-wine stain is often a target of ridicule by classmates, leading to
psychologic trauma. Pulsed-dye laser therapy often provides excellent
clearing of the port-wine stain, particularly if it is located on the
forehead.

Bibliography is available at Expert Consult.

596.4 Von Hippel-Lindau Disease
Mustafa Sahin

von Hippel-Lindau disease affects many organs, including the cerebel-
um, spinal cord, retina, kidney, pancreas, and epididymis. Its inci-
dence is around 1 in 36,000 newborns. It results from an autosomal-
dominant mutation affecting a tumor suppressor gene, VHL.
Approximately 80% of individuals with von Hippel-Lindau syndrome
have an affected parent, and approximately 20% have a de novo gene
mutation. Molecular testing is available and detects mutations in
almost 100% of probands.

The major neurologic features of the condition include cerebellar
hemangioblastomas and retinal angiomas. Patients with cerebellar
hemangioblastoma present in early adult life with symptoms and
signs of increased intracranial pressure. A smaller number of patients
have hemangioblastoma of the spinal cord, producing abnormalities
of proprioception and disturbances of gait and bladder dysfunction.
A CT or MRI scan typically shows a cystic cerebellar lesion with a
vascular mural nodule. Total surgical removal of the tumor is
curative.

Approximately 25% of patients with cerebellar hemangioblastoma
have retinal angiomas. Retinal angiomas are characterized by small
masses of thin-walled capillaries that are fed by large and tortuous
arterioles and venules. They are usually located in the peripheral retina
so that vision is unaffected. Exudation in the region of the angiomas
may lead to retinal detachment and visual loss. Retinal angiomas are
reated with photocoagulation and cryocoagulation, and both have
produced good results.

Cystic lesions of the kidneys, pancreas, liver, and epididymis as well
as pheochromocytoma are frequently associated with von Hippel-
Lindau disease. Renal carcinoma is the most common cause of death.
Regular follow-up and appropriate imaging studies are necessary to
identify lesions that may be treated at an early stage.

Bibliography is available at Expert Consult.

596.5 Linear Nevus Syndrome
Mustafa Sahin

This sporadic condition is characterized by a facial nevus and neuro-
developmental abnormalities. The nevus is located on the forehead and
nose and tends to be midline in its distribution. It may be quite faint
during infancy but later becomes hyperkeratotic, with a yellow-brown
appearance. Two thirds of the patients with linear nevus syndrome
demonstrate associated neurologic findings, including cortical dyspla-
sia, glial hamartomas, and low-grade gliomas. Cerebral and cranial
anomalies, predominantly hemimegalencephaly and enlargement of the
lateral ventricles, were reported in 72% of cases. The incidence of
epilepsy has been reported as high as 75% and intellectual disability as
high as 60%. Focal neurologic signs including hemiparesis and hom-
onymous hemianopia may also be seen.

Bibliography is available at Expert Consult.

596.6 PHACE Syndrome
Mustafa Sahin

See also Chapter 650.

The syndrome denotes posterior fossa malformations, hemangio-
mas, arterial anomalies, coarctation of the aorta and other cardiac
defects, and eye abnormalities. It is also referred to as PHACES syn-
drome when ventral developmental defects, including sternal clefting
and/or a supraumbilical raphe, are present. Large facial hemangiomas
may be associated with a Dandy-Walker malformation, vascular anom-
malies (coarctation of aorta, aplasia or hypoplastic carotid arteries, aneu-
rysmsal carotid dilation, aberrant left subclavian artery), glaucoma,
cataracts, microphthalmia, optic nerve hypoplasia, and ventral defects
(ster nal clefts). The facial hemangioma is typically ipsilateral to the
aortic arch. The Dandy-Walker malformation is the most common
developmental abnormality of the brain. Other anomalies include
hypoplasia or agenesis of the cerebellum, cerebellar vermis, corpus
callosum, cerebrum, and septum pellucidum. Cerebrovascular anom-
alyes can result in acquired, progressive vessel stenosis and acute ischemic stroke. According to a case series of 29 children with PHACE syndrome, 44% had language delay, 36% gross motor delay, and 8% fine motor delay; 52% had an abnormal neurologic exam, with speech
abnormalities as the most common finding. Overall, there is a female
predominance. The underlying pathogenesis of PHACE syndrome
remains unknown. Propranolol is starting to be used for treatment of
the infantile hemangiomas associated with PHACE syndrome.

Bibliography is available at Expert Consult.

596.7 Incontinentia Pigmenti
Mustafa Sahin

This rare, heritable, multisystem ectodermal disorder features derma-
tologic, dental, and ocular abnormalities. The phenotype is produced
by functional mosaicism caused by random X-inactivation of an
X-linked dominant gene that is lethal in males (IKBKG [inhibitor of
kappa B kinase gamma, previously NEMO] gene). The paucity of
affected males, the occurrence of female-to-female transmission, and
an increased frequency of spontaneous abortions in carrier females
support this supposition.

CLINICAL MANIFESTATIONS AND DIAGNOSIS
This disease has 4 phases, not all of which may occur in a given patient.
The 1st phase is evident at birth or in the 1st few wk of life and consists of erythematous linear streaks and plaques of vesicles (Fig.
596-12) that are most pronounced on the limbs and circumferentially

Bibliography
Bibliography
**Bibliography**

Bibliography

Differential diagnosis includes hypomelanosis of Ito, which presents with similar skin manifestations and is often associated with chromosomal mosaicism.

**MANAGEMENT**

The choice of investigative studies and the plan of management depend on the occurrence of particular noncutaneous abnormalities since the skin lesions are benign. The high incidence of associated major anomalies warrants genetic counseling.

*Bibliography is available at Expert Consult.*

---

**Figure 596-12 Whorled vesicular phase of incontinentia pigmenti.**

Diagnosis of incontinentia pigmenti is made on clinical grounds, although major and minor criteria have been established to aid in diagnosis. Wood's lamp examination may be useful in older children and adolescents to highlight pigmentary abnormalities. Clinical molecular testing is available, and in 80% of the affected patients a deletion that removes exons 4 through 10 of *IKBKG* gene can be detected.
Bibliography
Movement disorders are characterized by abnormal or excessive involuntary movements that may result in abnormalities in posture, tone, balance, or fine motor control. Most movement disorders in children are characterized by involuntary movements. These involuntary movements can represent the sole disease manifestation, or they may be one of many signs and symptoms.

Evaluation of movement disorders begins with a comprehensive history and careful neurologic examination. It is often difficult for children and caregivers to describe abnormal movements, which makes observation of the movements by the clinician an essential component of the evaluation. If the movements are not apparent at the time of the examination, video examples from home or school can be invaluable. With the increasing availability of high quality video capability on cellular phones, obtaining a short video is feasible for most families. Resources are available to guide families in gathering useful video data.

There is no specific diagnostic test to differentiate among movement disorders. The category of movement assists in localizing the pathologic process, whereas the onset, age, and degree of abnormal motor activity and associated neurologic findings help organize the investigation.

When considering the type of movement disorder, the following questions concerning the history and examination of the movement are helpful.

- What is the distribution of the movements across body parts?
- Are the movements symmetric?
- What is the speed of the involuntary movements? Are they rapid and fast or slow and sustained?
- When do the movements occur? Are they present at rest? Are they present with maintained posture or with voluntary actions?
- Are the movements seen in relation to certain postures or body positions?
- Do the abnormal movements occur only with specific tasks?
- Can the child voluntarily suppress the movements, even for a short time?
- Are the movements stereotyped?
- Are the movements rhythmic?
- What is the temporal pattern of the movements? Are they continuous or intermittent? Do they occur in discrete episodes?
- Are the involuntary movements preceded by an urge to make the movement?
- Do the movements persist during sleep?
- Are the movements associated with impairment of motor function?
- What factors aggravated or alleviate the movements?
Ataxias

Denia Ramirez-Montealegre and Jonathan W. Mink

Ataxia is the inability to make smooth, accurate, and coordinated movements, usually because of a dysfunction of the cerebellum, its inputs or outputs, sensory pathways in the posterior columns of the spinal cord, or a combination of these. Ataxias may be generalized or primarily affect gait or the hands and arms or trunk; they may be acute or chronic, acquired or genetic (Tables 597-2 to 597-5).

Signs and symptoms of ataxia include clumsiness, difficulty walking or sitting, falling to 1 side, slurred speech, hypotonia, intention tremor, dizziness, and delayed motor development. Genetic or chronic causes of cerebellar ataxia are often characterized by a long duration of symptoms, a positive family history, muscle weakness and abnormal gait, abnormal tone and strength, abnormal deep tendon reflexes, pes cavus, and sensory defects. Distinguishing ataxia from vestibular dysfunction may be difficult; however, labyrinth disorders are often characterized by severe vertigo, nausea and vomiting, position-induced vertigo, and a severe sense of unsteadiness.

Congenital anomalies of the posterior fossa, including the Dandy-Walker malformation, Chiari malformation, and encephalocele, are prominently associated with ataxia because of their destruction or replacement of the cerebellum (see Chapter 591.9). MRI is the method of choice for investigating congenital abnormalities of the cerebellum, vermis, and related structures. Agenesis of the cerebellar vermis presents in infancy with generalized hypotonia and decreased deep-tendon reflexes. Delayed motor milestones and truncal ataxia are typical. Joubert syndrome and related disorders are autosomal recessive disorders marked by developmental delay, hypotonia, abnormal eye movements, abnormal respirations, and a distinctive malformation of the cerebellum and brainstem that manifests as the "molar tooth sign" on MRI. Mutations in more than 21 different genes are associated with Joubert syndrome, but only approximately 50% of cases have a demonstrated causal mutation (see Chapter 591).

The major infectious causes of ataxia include cerebellar abscess, acute labyrinthitis, and acute cerebellar ataxia. Acute cerebellar ataxia occurs primarily in children 1-3 yr of age and is a diagnosis of exclusion. The condition often follows a viral illness, such as varicella virus, coxsackievirus, or echovirus infection by 2-3 wk and is thought to represent an autoimmune response to the viral agent affecting the cerebellum (see Chapters 250, 253, and 603). The onset is sudden, and the truncal ataxia can be so severe that the child is unable to stand or sit. Vomiting may occur initially, but fever and nuchal rigidity are absent. Horizontal nystagmus is evident in approximately 50% of cases and, if the child is able to speak, dysarthria may be impressive. Examination of the cerebrospinal fluid is typically normal at the onset of ataxia but a mild lymphocytic pleocytosis (10-30/mm³) is not unusual. Later in the course, the cerebrospinal fluid protein undergoes a moderate elevation. The ataxia begins to improve in a few weeks but may persist for as long as 3 mo and rarely longer than that. The incidence of acute cerebellar ataxia appears to have declined with increased rates of vaccination against varicella. The prognosis for complete recovery is excellent; a small number have long-term sequelae, including behavioral and speech disorders as well as ataxia and incoordination. Acute cerebellitis in contrast is a more severe form of cerebellar ataxia demonstrating abnormal MRI scans, more severe symptoms, and a poorer long-term prognosis. Infectious agents include Epstein-Barr virus, mycoplasma, mumps, and influenza virus, although in many the etiology is unknown; autoimmune cerebellitis may represent some of these unknown cases. Patients may present with ataxia, increased intracranial pressure from obstructive hydrocephalus, headache, and fever. Acute labyrinthitis may be difficult to differentiate from acute cerebellar ataxia in a toddler. The condition is associated with middle-ear infections and presents with intense vertigo, vomiting, and abnormalities in labyrinthine function.

Toxic causes of ataxia include alcohol, thallium (which is used occasionally in homes as a pesticide), and the anticonvulsants, particularly phenytoin and carbamazepine when serum levels exceed the usual therapeutic range.

Brain tumors (see Chapter 497), including tumors of the cerebellum and frontal lobe, as well as peripheral nervous system neuroblastoma, may present with ataxia. Cerebellar tumors cause ataxia because of direct disruption of cerebellar function or indirectly because of increased intracranial pressure from compression of the fourth ventricle. Frontal lobe tumors may cause ataxia as a consequence of destruction of the association fibers connecting the frontal lobe with the cerebellum or because of increased intracranial pressure. Neuroblastoma (see Chapter 498) may be associated with a paraneoplastic encephalopathy characterized by progressive ataxia, myoclonic jerks,
## Table 597-2  Selected Causes of Ataxia in Childhood

### CONGENITAL
- Agenesis of vermis of the cerebellum
- Aplasia or dysplasia of the cerebellum
- Basilar impression
- Cerebellar dysplasia with microgyria, macrogyria, or agyria
- Cervical spinal bifida with herniation of the cerebellum (Chiari malformation type 3)
- Chiari malformation
- Dandy-Walker syndrome
- Encephalocele
- Hydrocephalus (progressive)
- Hypoplasia of the cerebellum

### DEGENERATIVE AND/OR GENETIC
- Acute intermittent cerebellar ataxia
- Ataxia, retinitis pigmentosa, deafness, vestibular abnormality, and intellectual deterioration
- Ataxia-telangiectasia
- Biemond posterior column ataxia
- Cerebellar ataxia with deafness, anosmia, absent caloric responses, nonreactive pupils, and hyporeflexia
- Cockayne syndrome
- Dentate cerebellar ataxia (dyssynergia cerebellaris progressiva)
- Familial ataxia with macular degeneration
- Friedreich ataxia
- Hereditary cerebellar ataxia, intellectual retardation, choreoathetosis, and eunuchoidism
- Hereditary cerebellar ataxia with myotonia and cataracts
- Hypertrophic interstitial neuritis
- Marie ataxia
- Marinesco-Sjögren syndrome
- Multiple-system atrophy
- Progressive cerebellar ataxia and epilepsy
- Ramsay Hunt syndrome (myoclonic seizures and ataxia)
- Rousky-Lévy disease
- Spinocerebellar ataxia (SCA); olivopontocerebellar ataxias
- Vanishing white matter syndrome

### ENDOCRINOLOGIC
- Acquired hypothyroidism
- Cretinism

### INFECTIONOUS, POSTINFECTIOUS, INFLAMMATORY
- Acute cerebellar ataxia
- Acute disseminated encephalomyelitis
- Autoimmune (anti-glutamic acid decarboxylase, anti-γ-aminobutyric acid, receptor antibodies)
- Cerebellar abcess
- Cerebellitis
- Coxsackievirus
- Diphtheria

- Fisher syndrome
- Infectious mononucleosis (Epstein-Barr virus infection)
- Infectious polyneuropathy
- Japanese B encephalitis
- Mumps encephalitis
- Mycoplasma pneumonia
- Paraneoplastic (opsoclonus-myoclonus-ataxia syndrome)
- Pertussis
- Polio
- Postbacterial meningitis
- Rubella
- Tuberculosis
- Typhoid
- Varicella

### METABOLIC
- Abetalipoproteinemia
- Argininosuccinic aciduria
- Ataxia with vitamin E deficiency (AVED)
- Congenital disorders of glycosylation
- GM1; gangliosidosis (late)
- Hartnup disease
- Hyperalaninemia
- Hyperammonemia I and II (urea cycle defects)
- Hypoglycemia
- Kearns-Sayre syndrome
- Leigh disease
- Maple syrup urine disease (intermittent)
- Myoclonic epilepsy with ragged red fibers (MERRF)
- Metachromatic leukodystrophy
- Mitochondrial complex defects (I, III, IV)
- Multiple carboxylase deficiency (biotinidase deficiency)
- Neuronal ceroid-lipofuscinosis
- Neuropathy, ataxia, retinitis pigmentosa (NARP)
- Niemann-Pick disease (late infantile)
- 5-Oxoprolinuria
- Pyruvate decarboxylase deficiency
- Refsum disease
- Sialidosis
- Triose-phosphate isomerase deficiency
- Tryptophanuria
- Wernicke encephalopathy

### NEOPLASTIC
- Frontal lobe tumors
- Hemispheric cerebellar tumors
- Midline cerebellar tumors
- Neuroblastoma
- Pontine tumors (primarily gliomas)
- Spinal cord tumors

### PRIMARY PSYCHOGENIC
- Conversion reaction

### TOXIC
- Alcohol
- Benzodiazepines
- Carbamazepine
- Clonazepam
- Lead encephalopathy
- Neuroblastoma
- Phenobarbital
- Phenytin
- Primidone
- Tic paralysis poisoning

### TRAUMATIC
- Acute cerebellar edema
- Acute frontal lobe edema

### VASCULAR
- Angioblastoma of cerebellum
- Basilar migraine
- Cerebellar embolism
- Cerebellar hemorrhage
- Cerebellar thrombosis
- Posterior cerebellar artery disease
- Vasculitis
- von Hippel-Lindau disease

and opoclonus (norrhythmic, conjugate horizontal and vertical oscillations of the eyes).

Several metabolic disorders are characterized by ataxia, including atelalipoproteinemia, arginosuccinic aciduria, and Hartnup disease. Atelalipoproteinemia (Bassen-Kornzeig disease) begins in childhood with steatorrhea and failure to thrive (see Chapters 86.3 and 600). A blood smear shows acanthocytosis. Serum chemistries reveal decreased levels of cholesterol and triglycerides; serum β-lipoproteins are absent. Neurologic signs become evident by late childhood and consist of ataxia, retinitis pigmentosa, peripheral neuritis, abnormalities of position and vibration sense, muscle weakness, and intellectual disability. Vitamin E is undetectable in the serum of patients with neurologic symptoms.

Degenerative diseases of the central nervous system represent an important group of ataxic disorders of childhood because of the genetic consequences and poor prognosis. Ataxia-telangiectasia, an autosomal recessive condition, is the most common of the degenerative ataxias and is heralded by ataxia beginning at approximately age 2 yr and progressing to loss of ambulation by adolescence. Ataxia-telangiectasia is caused by mutations in the ATM gene located at 11q22-q23. ATM is a phosphatidylinositol-3 kinase that phosphorylates proteins involved in DNA repair and cell-cycle control. Occlusor apraxia of horizontal gaze, defined as difficulty shifting gaze from one object to another and overshooting the target with lateral movement of the head, followed by refixating the eyes, is a frequent finding, as is strabismus, hypometric saccade pursuit abnormalities, and nystagmus. Ataxia-telangiectasia may present with chorea (see Chapter 597.2) rather than ataxia. The telangiectasia becomes evident by mid-childhood and is found on the bulbar conjunctiva, over the bridge of the nose, and on the ears and exposed surfaces of the extremities. Examination of the skin shows a loss of elasticity. Abnormalities of immunologic function that lead to frequent sinopulmonary infections include decreased serum and secretory immunoglobulin (Ig) A as well as diminished IgG, IgG4, and IgE levels in more than 50% of patients. Children with ataxia-telangiectasia have a 50-100-fold increased risk of developing lymphoreticular tumors (lymphoma, leukemia, and Hodgkin disease) as well as brain tumors. Additional laboratory abnormalities include an increased incidence of chromosome breaks, particularly of chromosome 14, and elevated levels of α-fetoprotein. Death results from infection or tumor dissemination.

Friedreich ataxia is inherited as an autosomal-recessive disorder involving the spinocerebellar tracts, dorsal columns in the spinal cord, the pyramidial tracts, and the cerebellum and medulla. The majority of patients are homozygous for a GAA repeat expansion in the noncoding region of the gene coding for the mitochondrial protein frataxin. Mutations cause oxidative injury associated with excessive iron deposits in mitochondria. The onset of ataxia is somewhat later than in ataxia-telangiectasia, but usually occurs before age 10 yr. The ataxia is slowly progressive and involves the lower extremities to a greater degree than the upper extremities. The Romberg test result is positive; the deep-tendon reflexes are absent (particularly at the ankle), and the plantar response is typically extensor (Babinski sign). Patients develop
Chorea, meaning “dance-like” in Greek, refers to rapid, chaotic movements that seem to flow from 1 body part to another. Affected individuals exhibit motor impersistence, with difficulty keeping the movements that seem to flow from 1 body part to another. Chorea tends to occur both at rest and with action. Patients often attempt to incorporate the involuntary movements into more purposeful movements, making them appear fidgety. Chorea increases with stress and disappears in sleep. Chorea can be divided into primary (i.e., disorders in which chorea is the dominant symptom and the etiology is presumed to be genetic) and secondary forms, with the vast majority of pediatric cases falling into the latter category (Tables 597-6 and 597-7).

Sydenham chorea (St. Vitus dance) is the most common acquired chorea of childhood. It occurs in 10–20% of patients with acute rheumatic fever, typically weeks to months after a group A β-hemolytic streptococcal infection (see Chapter 183.1). Peak incidence is at age 8–9 yr, with a female predominance of 2:1. There is evidence that group A β-hemolytic streptococci promote the generation of cross-reactive or polyreactive antibodies through molecular mimicry between streptococcal and host antigens. Specifically, antibodies against the N-acetyl-β-D-glucosamine epitope (GlcNAc) of streptococcal group A carbohydrate target intracellular β-tubulin and extracellular lysoganglioside GM1, in human caudate-putamen preparations. These antibodies are also capable of directing calcio-calmodulin–dependent protein kinase II activation, which may cause the neurologic manifestations of Sydenham chorea by increasing dopamine release into the synapse.

The clinical hallmarks of Sydenham chorea are chorea, hypotonia, and emotional lability. Onset of the chorea is usually insidious but may be abrupt. Most patients have generalized chorea but the majority have asymmetric manifestations and up to 20% have hemichorea. Hypotonia manifests with the “pronator sign” (arms and palms turn outward when held overhead) and the “choreic hand” (spooning of the extended hand by flexion of the wrist and extension of the fingers). When chorea and hypotonia are severe, the child may be incapable of feeding, dressing, or walking without assistance. Speech is often involved, sometimes to the point of being unintelligible. Periods of uncontrollable crying and extreme mood swings are characteristic and may precede the onset of the movement disorder.

Continued
Sydenham chorea is a clinical diagnosis; a combination of acute and convalescent serum antistreptolysin O titers may help to confirm an acute streptococcal infection. Negative titers do not exclude the diagnosis. All patients with Sydenham chorea should be evaluated for carditis and started on long-term antibiotic prophylaxis (e.g., penicillin G benzathine 1.2 million units IM every 4 wk or penicillin V 250 mg PO twice daily) to decrease the risk of rheumatic heart disease with recurrence. For patients with chorea that is impairing, treatment options include valproate, carbamazepine, and dopamine receptor antagonists. Historically, there have been conflicting data regarding the efficacy of prednisone, intravenous immunoglobulin, and other immunomodulatory agents in Sydenham chorea, making it difficult to recommend their routine use. A more recent randomized, double-blinded study of 37 children with Sydenham chorea compared high-dose prednisone (2 mg/kg/day, max: 60 mg) for 4 wk vs a placebo and found that steroids significantly reduced time to remission (54.3 days vs 119.9 days in controls). There is no evidence that treatment with prednisone alters recurrence rate or long-term outcome.

Sydenham chorea usually resolves spontaneously within 6-9 mo, although it can persist for up to 2 yr and, in rare cases, can remain a lifelong condition. Relapse in the 1st few yr is relatively common, occurring in 37.9% of patients in 1 series. Remote recurrence of chorea is rare, but may be provoked by streptococcal infections, pregnancy (chorea gravidarum), or oral contraceptive use.

Although much rarer than Sydenham chorea, systemic lupus erythematosus (see Chapter 158) is a well-known cause of chorea in children. In some cases, chorea may be the presenting sign of systemic lupus erythematosus. A recent retrospective study of a large pediatric lupus cohort examined the prevalence of antiphospholipid antibodies and evaluated their association with neuropsychiatric symptoms. There was a significant association between a persistently positive lupus anticoagulant and chorea (p = 0.02); however, only 2 of the 137 patients in the cohort had chorea. Regardless, a child with chorea of unknown cause should be investigated for the presence of antiphospholipid antibodies.

Additional causes of secondary chorea include metabolic (hyperthyroidism, hypoparathyroidism), infectious (Lyme disease), immunemediated (systemic lupus erythematosus; anti–N-methyl-D-aspartate receptor antibody syndrome), vascular (stroke, moyamoya disease), heredodegenerative disorders (Wilson disease), and drugs (Table 597-8). Although chorea is a hallmark of Huntington disease in adults, children who develop Huntington disease tend to present with rigidity and bradykinesia (Westphal variant) or dystonia rather than chorea.

**Athetosis** is characterized by slow, continuous, writhing movements that repeatedly involve the same body part(s), usually the distal...
extremities, face, neck, or trunk. Like chorea, athetosis may occur at rest and is often worsened by voluntary movement. Because athetosis tends to co-occur with other movement disorders, such as chorea (choreathetosis) and dystonia, it is often difficult to distinguish as a discrete entity. Choreathetosis is associated with cerebral palsy, kernicterus, and other forms of basal ganglia injury; therefore, it is often seen in conjunction with rigidity—increased muscle tone that is equal in the flexors and extensors in all directions of passive movement regardless of the velocity of the movement. This is to be differentiated from spasticity, a velocity-dependent in all directions of passive movement.

Tremor is a rhythmic, oscillatory movement around a central point or plane that results from the action of antagonist muscles. Tremor can affect the extremities, head, trunk, or voice and can be classified by both its frequency (slow [4 Hz], intermediate [4-7 Hz], and fast [>7 Hz]) and by the context in which it is most pronounced. Rest tremor is maximal when the affected body part is inactive and supported against gravity, whereas postural tremor is most notable when the patient sustains a position against gravity. Action tremor occurs with performance of a voluntary activity and can be subclassified into simple kinetic tremor, which occurs with limb movement, and intention tremor, which occurs as the patient’s limbs approaches a target and is a feature of cerebellar disease.

Essential tremor (ET) is the most common movement disorder in adults, and 50% of persons diagnosed with ET report an onset in childhood; thus ET may be the most common tremor disorder in children as well. Clinical experience in pediatric movement disorders clinic suggests that ET is more common in the pediatric population than the literature would suggest. ET is an autosomal-dominant condition with variable expressivity but complete penetrance by the age of 60 yr. Although the genetics of ET are not fully understood, at least 3 different genes—EMT1 on chromosome 3q13, EMT2 on chromosome 2p22-25, and LINGO1 on chromosome 15q24—are linked to the condition. Based on functional imaging studies, the defect is thought to localize to cerebellar circuits.

ET is characterized by a slowly progressive, bilateral, 4-9 Hz postural tremor that involves the upper extremities and occurs in the absence of other known causes of tremor. Mild asymmetry is common, but ET is rarely unilateral. ET may be worsened by actions, such as trying to pour water from cup to cup. Affected adults may report a history of ethanol responsiveness. Most young children present for evaluation because a parent, teacher, or therapist has noticed the tremor, rather than the tremor causes impairment. Most children with ET do not require pharmacologic intervention. If they are having difficulty with their handwriting or self-feeding, an occupational therapy evaluation and/or assistive devices, such as wrist rests and weighted silverware, may be helpful. Teenagers tend to report more impairment from ET. Teenagers who do require pharmacotherapy usually respond to the same medications that are used in adults—propranolol and primidone. Propranolol, which is generally considered the first-line treatment, can be started at 20–40 mg daily and titrated to effect, with most patients responding to doses of 60-80 mg/day. Propranolol should not be used in patients with reactive airway disease. Primidone can be started at 12.5-25 mg at bedtime and increased gradually in a twice daily schedule. Most patients respond to doses of 50-200 mg/day. Other treatments options for ET reported in the adult literature include atenolol, gabapentin, topiramate, and alprazolam. Surgical treatments, which include deep brain stimulation of the thalamus and unilateral thalamotomy, are generally reserved for adults with medically refractory disabling tremor.

In addition to ET, there are numerous secondary etiologies of tremor in children (Table 597-9). Holmes tremor, previously referred to as midbrain or rubral tremor, is characterized by a slow frequency, high-amplitude tremor that is present at rest and with intention. It is a symptomatic tremor, which usually results from lesions of the brainstem, cerebellum, or thalamus. Psychogenic tremor is distinguished by its variable appearance, abrupt onset and remission, nonprogressive course, and association with selective but not task-specific disabilities. In some cases, tremor may even occur as a manifestation of another movement disorder, as is seen with position- or task-specific tremor (e.g., writing tremor), dystonic tremor, and myoclonic tremor.

When evaluating a child with tremor, it is important to screen for common metabolic disturbances, including electrolyte abnormalities and thyroid disease, assess the child’s caffeine intake, and review the child’s medication list for known tremor-inducing agents. It is also critical to exclude Wilson disease in teenagers with characteristic “wing-beating” tremor, as this is a treatable condition.

### 597.3 Dystonia

**Erika F. Augustine and Jonathan W. Mink**

Dystonia is a disorder of movement characterized by sustained muscle contraction, frequently causing twisting and repetitive movements or abnormal postures. Major causes of dystonia include primary generalized dystonia, medications, metabolic disorders, and perinatal asphyxia (Tables 597-10 and 597-11).

**INHERITED PRIMARY DYSTONIAS**

Primary generalized dystonia, also referred to as primary torsion dystonia or dystonia musculorum deformans, is caused by a group of genetic disorders with onset in childhood. One form, which occurs more commonly in the Ashkenazi Jewish population, is caused by a dominant mutation in the DYT1 gene coding for the adenosine A1 receptor.

triphosphate (ATP) binding protein torsinA. The initial manifestation of DYT1 dystonia is often intermittent unilateral posturing of a lower extremity, which assumes an extended and rotated position. Ultimately, all 4 extremities and the axial musculature can be affected, but the dystonia may also remain localized to one limb. Cranial involvement can occur in DYT1 dystonia, but it is uncommon compared to non-DYT1 dystonias. There is a wide clinical spectrum, varying even within families. If a family history of dystonia is absent, the diagnosis should still be considered, given the intrafamilial variability in clinical expression.

More than a dozen loci for genes for torsion dystonia have been identified (DYT1-DYT24). One is the autosomal dominant disorder dopa-responsive dystonia (DRD, DYT5a), also called Segawa syndrome. The gene for DRD codes for guanosine triphosphate cyclohydrolase 1, the rate-limiting enzyme for tetrahydrobiopterin synthesis, which is a cofactor for synthesis of the neurotransmitters dopamine

and serotonin. Thus, the genetic mutation results in dopamine deficiency. The hallmark of the disorder, particularly in adolescents and adults, is diurnal variation: symptoms worsen as the day progresses and may transiently improve with sleep. Early-onset patients, who tend to present with delayed or abnormal gait from dystonia of a lower extremity, can easily be confused with patients with dystonic cerebral palsy. It should be noted that in the presence of a progressive dystonia, diurnal fluctuation, or if loss of previously achieved motor skills occurs, a prior diagnosis of cerebral palsy should be reexamined. DRD responds dramatically to small daily doses of levodopa. The responsiveness to levodopa is a sustained benefit, even if the diagnosis is delayed several years, as long as contractures have not developed.

**Myoclonus dystonia (DYTT11)**, caused by mutations in the epsilon-sarcoglycan (SCGE) gene, is characterized by dystonia involving the upper extremities, head, and/or neck, as well as myoclonic movements in these regions. Although a combination of myoclonus and dystonia typically occurs, each manifestation can present in isolation. When repetitive, the myoclonus may take on a tremor-like appearance, termed dystonic tremor. Improvement in symptoms following alcohol ingestion, reported by affected adult family members, may be a helpful clue to this diagnosis.

Common to the inherited dystonias, there is considerable intrafamilial variability in clinical manifestations, distribution, and severity of dystonia. In primary dystonias, although the main clinical features are motor, there may be an increased risk for major depression. Anxiety, obsessive-compulsive disorder, and depression have all been reported in the myoclonus–dystonia syndrome. Screening for psychiatric comorbidities cannot be overlooked in this population.

**DRUG-INDUCED DYSTONIAS**

A number of medications are capable of inducing involuntary movements, drug-induced movement disorders, in children and adults. Dopamine-blocking agents, including antipsychotics (e.g., haloperidol) and antiepileptics (e.g., carbamazepine, phenytoin), as well as atypical antipsychotics (e.g., risperidone) can produce acute dystonic reactions or delayed (tardive) drug-induced movement disorders. **Acute dystonic reactions**, occurring in the 1st days of exposure, typically involve the face and neck, manifesting as torticollis, retrocolis, orofacial dystonia, or tongue protrusion. Life-threatening presentations with laryngospasm and airway compromise can also occur, requiring prompt recognition and treatment of this entity. Intravenous diphenhydramine, 1-2 mg/kg/dose, may rapidly reverse the drug-related dystonia. The high potency of the dopamine blocker, young age, and prior dystonic reactions may be predisposing factors. Acute dystonic reactions have also been described with cetrizine.

Severe rigidity combined with high fever, autonomic symptoms (tachycardia, diaphoresis), delirium, and dystonia are signs of neuroleptic malignant syndrome, which typically occurs a few days after starting or increasing the dose of a neuroleptic drug, or in the setting of withdrawal from a dopaminergic agent. In contrast to acute dystonic reactions, which take place within days, neuroleptic malignant syndrome occurs within a month of medication initiation or dose increase.

Delayed onset involuntary movements, **tardive dyskinesias**, develop in the setting of chronic (>3 mo duration) neuroleptic use. Involvement of the face, particularly the mouth, lips, and/or jaw with chewing or tongue thrusting is characteristic. The risk of tardive dyskinesia, which is much less frequent in children compared to adults, increases as medication dose and duration of treatment increase. There are data to suggest that children with autism spectrum disorders may also be at increased risk for this drug-induced movement disorders. Unlike acute dystonic reactions and neuroleptic malignant syndrome, discontinuation of the offending agent may not result in clinical improvement. In these patients, use of dopamine-depleters, such as reserpine or tetrabenazine, may prove helpful.

Therapeutic doses of phenytoin or carbamazepine rarely cause progressive dystonia in children with epilepsy, particularly in those who have an underlying structural abnormality of the brain. During evaluation of new onset dystonia, a careful history of prescriptions and potential medication exposures is critical.

### CEREBRAL PALSY

See Chapter 598.

### METABOLIC DISORDERS

**Disorders of monamine neurotransmitter metabolism**, of which DRD is one, present in infancy and early childhood with dystonia, hypotonia, oculogyric crises, and/or autonomic symptoms. The more common disorders among this group of rare diseases include DRD, tyrosine hydroxylase deficiency, and aromatic amino acid decarboxylase deficiency. Abnormalities of the dopamine transporter (DAT) can also present in infancy with dystonia. Detailed discussion is beyond the scope of this chapter; reviews, however, are available for reference.

**Wilson disease** is an autosomal recessive inborn error of copper transport characterized by cirrhosis of the liver and degenerative changes in the central nervous system, particularly the basal ganglia (see Chapter 357.2). It has been determined that there are multiple mutations in the Wilson disease gene (WND), accounting for the variability in presentation of the condition. The neurologic manifestations of Wilson disease rarely appear before age 10 yr, and the initial sign is often progressive dystonia. Tremors of the extremities develop, unilaterally at first, but they eventually become coarse, generalized, and incapacitating. Other neurologic signs of Wilson disease relate to progressive basal ganglia disease, such as parkinsonism, dystarthritis, dysphonia, and choreoathetosis. Less frequent are ataxia and pyramidal signs. The MRI or CT scan shows ventricular dilation in advanced cases with atrophy of the cerebral cortex, cerebellum, and/or brainstem, along with signal intensity change in the basal ganglia, thalamus, and/or brainstem, particularly the midbrain.

Pantothenate kinase–associated neurodegeneration (formerly known as Hallervorden-Spatz disease) is a rare autosomal recessive neurodegenerative disorder. Many patients have mutations in pantothenate kinase 2 (PANK2) localized to mitochondria in neurons. The condition usually begins before 6 yr of age and is characterized by rapidly progressive dystonia, rigidity, and choreoathetosis. Spasticity, extensor plantar responses, dysarthria, and intellectual deterioration become evident during adolescence, and death usually occurs by early adulthood. MRI shows lesions of the globus pallidus, including low signal intensity in T2-weighted images (corresponding to iron pigments) and an anteromedial area of high signal intensity (tissue necrosis and edema), or “eye-of-the-tiger” sign (Fig. 597-1). Neuropathologic examination indicates excessive accumulation of iron-containing pigments in the globus pallidus and substantia nigra. More recently, similar disorders of high brain iron content without PANK2 mutations, including infantile neuroaxonal dystrophy, neuroferritinopathy, and aceruloplasminemia, have been grouped as disorders of neurodegeneration with brain iron accumulation. Patterns of iron deposition visualized by brain MRI have shown utility in differentiating these diseases.

**Biotin-responsive basal ganglia disease** manifests with episodes of acute dystonia, external ophthalmoplegia, and encephalopathy. SLC19A3 is the responsible mutated gene. MRI demonstrates involvement of the basal ganglia, with vasogenic edema and the “bat-wing” sign (Fig. 597-2). Treatment with biotin and thiamine results in improvement in 2–4 days.

Although dystonia may present in isolation as the first sign of a metabolic or neurodegenerative disorder, this group of diseases should be considered mainly in those who demonstrate signs of systemic disease, (e.g., organomegaly, short stature, hearing loss, vision impairment, epilepsy), those with episodes of severe illness, evidence of regression, or cognitive impairment. Table 597-11 outlines additional features suggestive of specific disorders.

### OTHER DISORDERS

Although uncommon, movement disorders, including dystonia, may be part of the presenting symptoms of complex regional pain syndrome. Onset of involuntary movements within 1 yr of the traumatic event, affected lower limb, pain disproportionate to inciting event, and changes in the overlying skin and blood flow to the affected area suggest complex regional pain syndrome. Although sustained dystonia...
patients are also affected by episodes of dystonia, ranging from minutes to days in duration. On average, both features of the disorder commence at approximately 6 mo of age. Episodic abnormal eye movements are observed in a large proportion of patients (93%) with onset as early as the 1st wk of life. Alternating hemiplegia of childhood is associated with mutations in the \( \text{ATP1A2} \) and \( \text{ATP1A3} \) genes. Alternating hemiplegia of childhood can similarly be triggered by fluctuations in temperature, certain foods, or water exposure. Over time, epilepsy and cognitive impairment emerge, and the involuntary movements change from episodic to constant. Infantile onset and the paroxysmal nature of symptoms early in the disease course are key features to this diagnosis.

Finally, although a diagnosis of exclusion, the presence of odd movements or selective disability may indicate a psychogenic dystonia in older children. There is considerable overlap in features of organic and can produce pain or discomfort, complex regional pain syndrome should be considered in those who have a prominent component of pain and recent history of trauma to the affected limb.

There are disorders unique to childhood that warrant exploration in this section. **Benign paroxysmal torticollis of infancy** is characterized by recurrent episodes of cervical dystonia beginning in the 1st few mo of life. The torticollis may alternate sides from 1 episode to the next and may also persist during sleep. Associated signs and symptoms include irritability, pallor, vomiting, vertigo, ataxia, and occasionally limb dystonia. Family history is often notable for migraine and/or motion sickness in 1st-degree relatives. Despite the high frequency of spells, imaging studies are normal, and the outcome is uniformly benign with resolution by 3 yr of age.

**In alternating hemiplegia of childhood**, episodic hemiplegia affecting either side of the body is the hallmark of the disorder. However,
psychogenic movement disorders, making the diagnosis difficult to establish. For instance, both organic and psychogenic movement disorders have the potential to worsen in the setting of stress and may dissipate with relaxation or sleep. History should include review of recent stressors, psychiatric symptoms, and exposure to others with similar disorders. On examination, a changing movement disorder, inconsistent motor or sensory exam, or response to suggestion, are supportive of a possible psychogenic movement disorder. Early recognition of this disorder may lessen morbidity caused by unnecessary diagnostic and interventional procedures.

**TREATMENT**

Children with generalized dystonia, including those with involvement of the muscles of swallowing, may respond to the anticholinergic agent trihexyphenidyl (Artane). Titration occurs slowly over the course of months in an effort to limit untoward side effects, such as urinary retention, mental confusion, or blurred vision. Additional drugs that have been effective include levodopa and diazepam. Segmental dystonia, such as torticollis, often responds well to botulinum toxin injections. Intrathecal baclofen delivered through implantable constant infusion pump may be helpful in some patients. Deep brain stimulation with leads implanted in the globus pallidus is most helpful for children with severe primary generalized dystonia. Recent data suggest, however, that deep brain stimulation may also be of benefit in children with secondary dystonias, such as cerebral palsy.

In the case of drug-induced dystonias, removal of the offending agent and treatment with intravenous diphenhydramine typically suffices. For neuroleptic malignant syndrome, dantrolene may be indicated.

EPISTEMOLOGY AND ETIOLOGY

CP is the most common and costly form of chronic motor disability that begins in childhood; data from the Centers for Disease Control and Prevention indicate that the incidence is 3.6 per 1,000 children with a male:female ratio of 1.4:1. The Collaborative Perinatal Project, in which approximately 45,000 children were regularly monitored from in utero to the age of 7 yr, found that most children with CP had been born at term with uncomplicated labors and deliveries. In 80% of cases, features were identified pointing to antenatal factors causing abnormal brain development. A substantial number of children with CP had congenital anomalies external to the central nervous system (CNS). Fewer than 10% of children with CP had evidence of intrapartum asphyxia. Intrauterine exposure to maternal infection (chorioamnionitis, inflammation of placental membranes, umbilical cord inflammation, foul-smelling amniotic fluid, maternal sepsis, temperature >38°C [100.4°F] during labor, urinary tract infection) was associated with a significant increase in the risk of CP in normal birthweight infants. Elevated levels of inflammatory cytokines have been reported in heelstick blood collected at birth from children who later were identified with CP. Genetic factors may contribute to the inflammatory cytokine response, and a functional polymorphism in the interleukin-6 gene is associated with a higher rate of CP in term infants.

The prevalence of CP has increased somewhat as a result of the enhanced survival of very premature infants weighing <1,000 g, who go on to develop CP at a rate of approximately 15 per 100. However, the gestational age at birth-adjusted prevalence of CP among 2 yr old former premature infants born at 20-27 wk of gestation has decreased over the past decade. The major lesions that contribute to CP in preterm infants are intracerebral hemorrhage and periventricular leukomalacia (PVL). Although the incidence of intracerebral hemorrhage has declined significantly, PVL remains a major problem. PVL reflects the enhanced vulnerability of immature oligodendroglia in premature infants to oxidative stress caused by ischemia or infectious/inflammatory insults. White matter abnormalities (loss of volume of periventricular white matter, extent of cystic changes, ventricular dilation, thinning of the corpus callosum) present on MRI at 40 wk of gestational age among former preterm infants are a predictor of later CP.

In 2006, the European Cerebral Palsy Study examined prenatal and perinatal factors as well as clinical findings and results of MRI in a contemporary cohort of more than 400 children with CP. In agreement with the Collaborative Perinatal Project study, more than half the children with CP in this study were born at term, and less than 20% had clinical or brain imaging indicators of possible intrapartum factors such as asphyxia. The contribution of intrapartum factors to CP is higher in some underdeveloped regions of the world. Also in agreement with earlier data, antenatal infection was strongly associated with CP and 39.5% of mothers of children with CP reported having an infection during the pregnancy, with 19% having evidence of a urinary tract infection and 11.5% reporting taking antibiotics. Multiple pregnancy was also associated with a higher incidence of CP and 12% of the cases in the European CP study resulted from a multiple pregnancy, in contrast to a 1.5% incidence of multiple pregnancy in the study. Other studies have also documented a relationship between multiple births and CP, with a rate in twins that is 5-8 times greater than in singleton pregnancies and a rate in triplets that is 20-47 times greater. Death of a twin in utero carries an even greater risk of CP that is 8 times that of a pregnancy in which both twins survive and approximately 60 times the risk in a singleton pregnancy. Infertility treatments are also associated with a higher rate of CP; probably because these treatments are often associated with multiple pregnancies. Among children from multiple pregnancies, 24% were from pregnancies after infertility treatment compared with 3.4% of the singleton pregnancies in the study. CP is more common and more severe in boys compared to girls and this effect is enhanced at the extremes of body weight. Male infants with intrauterine growth retardation and a birthweight less than the 3rd percentile are 16 times more likely to have CP than males with optimal growth, and infants with weights above the 97th percentile are 4 times more likely to have CP.

CLINICAL MANIFESTATIONS

CP is generally divided into several major motor syndromes that differ according to the pattern of neurologic involvement, neuropathology, and etiology (Table 598-1). The physiologic classification identifies the major motor abnormality, whereas the topographic taxonomy indicates the involved extremities. CP is also commonly associated with a spectrum of developmental disabilities, including intellectual impairment, epilepsy, and visual, hearing, speech, cognitive, and behavioral abnormalities. The motor handicap may be the least of the child’s problems.

Infants with spastic hemiplegia have decreased spontaneous movements on the affected side and show hand preference at a very early age. The arm is often more involved than the leg and difficulty in hand manipulation is obvious by 1 yr of age. Walking is usually delayed until 18-24 mo, and a circumductive gait is apparent. Examination of the extremities may show growth arrest, particularly in the hand and thumb, especially if the contralateral parietal lobe is abnormal, because extremity growth is influenced by this area of the brain. Spasticity refers to the quality of increased muscle tone, which increases with the speed of passive muscle stretching and is greatest in antigravity muscles. It is apparent in the affected extremities, particularly at the ankle, causing an equinovarus deformity of the foot. An affected child often walks on tiptoe because of the increased tone in the antigravity gastrocnemius muscles, and the affected upper extremity assumes a flexed posture when the child runs. Ankle clonus and a Babinski sign may be present, the deep tendon reflexes are increased, and weakness of the hand and foot dorsiflexors is evident. About one-third of patients with spastic hemiplegia have a seizure disorder that usually develops in the 1st yr or 2; approximately 25% have cognitive abnormalities including mental retardation. MRI is far more sensitive than CT for most lesions seen with CP, although a CT scan may be useful for detecting calcifications associated with congenital infections. In the European CP study, 34% of children with hemiplegia had injury to the white matter that probably dated to the in utero period and 27% had a focal lesion that may have resulted from a stroke. Other children with hemiplegic CP had had malformations from multiple causes including infections (e.g., cytomegalovirus), lissencephaly, polymicrogyria, schizencephaly, or cortical dysplasia. Focal cerebral infarction (stroke) secondary to intrauterine or perinatal thromboembolism related to thrombophilic disorders, like the presence of anticardiolipin antibodies, is an important cause of hemiplegic CP (see Chapter 601). Family histories suggestive of thrombosis and inherited clotting disorders, such as factor V Leiden mutation, may be present and evaluation of the mother may provide information valuable for future pregnancies and other family members.

Spastic diplegia is bilateral spasticity of the legs that is greater than in the arms. Spastic diplegia is strongly associated with damage to the immature white matter during the vulnerable period of immature oligodendroglia between 20-34 wk of gestation. However, approximately 15% of cases of spastic diplegia result from in utero lesions in infants who go on to delivery at term. The first clinical indication of spastic diplegia is often noted when an affected infant begins to crawl. The child uses the arms in a normal reciprocal fashion but tends to drag the legs behind more as a rudder (commando crawl) rather than using the normal 4-limbed crawling movement. If the spasticity is severe, application of a diaper is difficult because of the excessive adduction of the hips. If there is paraspinal muscle involvement, the child may be unable to sit. Examination of the child reveals spasticity in the legs with brisk reflexes, ankle clonus, and a bilateral Babinski sign. When the child is suspended by the axillae, a scissoring posture of the lower extremities is maintained. Walking is significantly delayed, the feet are held in a position of equinovarus, and the child walks on tiptoe. Severe spastic diplegia is characterized by disuse atrophy and impaired growth of the lower extremities and by disproportionate growth with normal development of the upper torso. The prognosis for normal intellectual development for these patients is good, and the likelihood of seizures is minimal. Such children often have learning disabilities and deficits in other abilities, such as vision, because of disruption of multiple white matter pathways that carry sensory as well as motor information.

The most common neuropathologic finding in children with spastic diplegia is PVL, which is visualized on MRI in more than 70% of cases. MRI typically shows scarring and shrinkage in the periventricular white matter with compensatory enlargement of the cerebral ventricles. However, neuropathology has also demonstrated a reduction in oligodendroglia in more widespread subcortical regions beyond the periventricular zones, and these subcortical lesions may contribute to the learning problems these patients can have. MRI with diffusion tensor imaging is being used to map white matter tracks more precisely in patients with spastic diplegia, and this technique has shown that thalamocortical sensory pathways are often injured as severely as motor corticospinal pathways (Fig. 598-1). These observations have led to greater interest in the importance of sensory deficits in these patients, which may be important for designing rehabilitative techniques.

Spastic quadriplegia is the most severe form of CP because of marked motor impairment of all extremities and the high association with intellectual disability and seizures. Swallowing difficulties are common as a result of supranuclear bulbar palsies, often leading to aspiration pneumonia. The most common lesions seen on pathologic examination or on MRI scanning are severe PVL and multicystic cortical encephalomalacia. Neurologic examination shows increased tone and spasticity in all extremities, decreased spontaneous movements, brisk reflexes, and plantar extensor responses. Flexion contractures of the knees and elbows are often present by late childhood. Associated

</table>
Athetoid CP, also called choreoathetoid, extrapyramidal, or dyskinetic CP, is less common than spastic CP and makes up approximately 15-20% of patients with CP. Affected infants are characteristically hypotonic with poor head control and marked head lag and develop variably increased tone with rigidity and dystonia over several years. The term dystonia refers to the abnormality in tone in which muscles are rigid throughout their range of motion and involuntary contractions can occur in both flexors and extensors leading to limb positioning in fixed postures. Unlike spastic diplegia, the upper extremities are generally more affected than the lower extremities in extrapyramidal CP. Feeding may be difficult, and tongue thrust and drooling may be prominent. Speech is typically affected because the oropharyngeal muscles are involved. Speech may be absent or sentences are slurred, and voice modulation is impaired. Generally, upper motor neuron signs are not present, seizures are uncommon, and intellect is preserved in many patients. This form of CP is also referred to in Europe as dyskinetic CP and is the type most likely to be associated with birth asphyxia. In the European CP study, 76% of patients with this form of CP had lesions in the basal ganglia and thalamus. Extrapyramidal CP secondary to acute intrapartum near-total asphyxia is associated with bilaterally symmetric lesions in the posterior putamen and ventrolateral thalamus. These lesions appear to be the correlate of the neuropsychologic lesion called status marmoratus in the basal ganglia. Athetoid CP can also be caused by kernicterus secondary to high levels of bilirubin, and in this case the MRI scan shows lesions in the globus pallidus bilaterally. Extrapyramidal CP can also be associated with lesions in the basal ganglia and thalamus caused by metabolic genetic disorders such as mitochondrial disorders and glutaric aciduria. MRI scanning and possibly metabolic testing are important in the evaluation of children with extrapyramidal CP to make a correct etiologic diagnosis. In patients with dystonia who have a normal MRI, it is important to have a high level of suspicion for dihydroxyphenylalanine (DOPA)-responsive dystonia (Segawa disease), which causes prominent dystonia that can resemble CP. These patients typically have diurnal variation in their signs with worsening dystonia in the legs during the day; however, this may not be prominent. These patients can be tested for a response to small doses of L-dopa and/or cerebrospinal fluid can be sent for neurotransmitter analysis.

Associated comorbidities are common and include pain (in 75%), cognitive disability (50%), hip displacement (30%), seizures (25%), behavioral disorders (25%), sleep disturbances (20%), visual impairment (19%), and hearing impairment (4%).

**DIAGNOSIS**

A thorough history and physical examination should preclude a progressive disorder of the CNS, including degenerative diseases, metabolic disorders, spinal cord tumor, or muscular dystrophy. The possibility of anomalies at the base of the skull or other disorders affecting the cervical spinal cord needs to be considered in patients with little involvement of the arms or cranial nerves. An MRI scan of the brain is indicated to determine the location and extent of structural lesions or associated congenital malformations; an MRI scan of the spinal cord is indicated if there is any question about spinal cord pathology. Additional studies may include tests of hearing and visual function. Genetic evaluation should be considered in patients with congenital malformations (chromosomes) or evidence of metabolic disorders (e.g., amino acids, organic acids, MR spectroscopy). In addition to the genetic disorders mentioned earlier that can present as CP,
the urea cycle disorder arginase deficiency is a rare cause of spastic diplegia and a deficiency of sulfite oxidase or molybdenum cofactor can present as CP caused by perinatal asphyxia. Tests to detect inherited thrombophilic disorders may be indicated in patients in whom an in utero or neonatal stroke is suspected as the cause of CP.

Because CP is usually associated with a wide spectrum of developmental disorders, a multidisciplinary approach is most helpful in the assessment and treatment of such children.

**TREATMENT**

Some progress has been made in both prevention of CP before it occurs and treatment of children with the disorder. Preliminary results from controlled trials of magnesium sulfate given intravenously to mothers in premature labor with birth imminent before 32 wk gestation showed significant reduction in the risk of CP at 2 yr of age. Nonetheless, one study that followed preterm infants whose mothers received magnesium sulfate demonstrated no benefit in terms of the incidence of CP and abnormal motor, cognitive, or behavioral function at school age. Furthermore, several large trials have shown that cooling term infants with hypoxic–ischemic encephalopathy to 33.3°C (91.9°F) for 3 days, starting within 6 hr of birth, reduces the risk of dyskinetic or spastic quadriplegia form of CP.

For children who have a diagnosis of CP, a team of physicians, including neurodevelopmental pediatricians, pediatric neurologists, and physical medicine and rehabilitation specialists, as well as occupational and physical therapists, speech pathologists, social workers, educators, and developmental psychologists, is important to reduce abnormalities of movement and tone and to optimize normal psychomotor development. Parents should be taught how to work with their child in daily activities such as feeding, carrying, dressing, bathing, and playing in ways that limit the effects of abnormal muscle tone. They also need to be instructed in the supervision of a series of exercises designed to prevent the development of contractures, especially a tight Achilles tendon. Physical and occupational therapies are useful for promoting mobility and the use of the upper extremities for activities of daily living. Speech language pathologists promote acquisition of a functional means of communications. These therapists help children to achieve their potential and often recommend further evaluations and adaptive equipment.

Children with spastic diplegia are treated initially with the assistance of adaptive equipment, such as walkers, poles, and standing frames. If a patient has marked spasticity of the lower extremities or evidence of hip dislocation, consideration should be given to performing surgical soft-tissue procedures that reduce muscle spasm around the hip girdle, including an adductor tenotomy or psoas transfer and release. A rhizotomy procedure in which the roots of the spinal nerves are divided produces considerable improvement in selected patients with severe spastic diplegia (Fig. 598-2). A tight heel cord in a child with spastic hemiplegia may be treated surgically by tenotomy of the Achilles tendon. Quadriplegia is managed with motorized wheelchairs, special feeding devices, modified typewriters, and customized seating arrangements. The function of the affected extremities in children with hemiplegic CP can often be improved by therapy in which movement of the good side is constrained with casts while the impaired extremities perform exercises which induce improved hand and arm functioning. This constraint-induced movement therapy is effective in patients of all ages.

Several drugs have been used to treat spasticity, including the benzodiazepines and baclofen. These medications have beneficial effects in some patients but can also cause side effects such as sedation for benzodiazepines and lowered seizure threshold for baclofen. Several drugs can be used to treat spasticity, including oral diazepam (0.01-0.3 mg/kg/day, divided bid or qid), baclofen (0.2-2 mg/kg/day, divided bid or tid) or dantrolene (0.5-10 mg/kg/day, bid). Small doses of levodopa (0.5-2 mg/kg/day) can be used to treat dystonia or DOPA-responsive dystonia. Artane (trihexyphenidyl, 0.25 mg/day, divided bid or tid and titrated upward) is sometimes useful for treating dystonia and can increase use of the upper extremities and vocalizations. Reserpine (0.01-0.02 mg/kg/day, divided bid to a maximum of 0.25 mg daily) or tetrabenazine (12.5-25.0 mg, divided bid or tid) can be useful for hyperkinetic movement disorders including athetosis or chorea.

Intrathecal baclofen delivered with an implanted pump has been used successfully in many children with severe spasticity, and can be useful because it delivers the drug directly around the spinal cord where it reduces neurotransmission of afferent nerve fibers. Direct delivery to the spinal cord overcomes the problem of CNS side effects caused by the large oral doses needed to penetrate the blood–brain barrier. This therapy requires a team approach and constant follow-up for complications of the infusion pumping mechanism and infection. Botulinum toxin injected into specific muscle groups for the management of spasticity shows a very positive response in many patients. Botulinum toxin injected into salivary glands may also help reduce the severity of drooling, which is seen in 10-30% of patients with CP and has been traditionally treated with anticholinergic agents. Patients with rigidity, dystonia, and spastic quadriparesis sometimes respond to levodopa, and children with dystonia may benefit from carbamazepine or trihexyphenidyl. Hyperbaric oxygen has not been shown to improve the condition of children with CP.

Communication skills may be enhanced by the use of Bliss symbols, talking typewriters, electronic speech generating devices, and specially adapted computers including artificial intelligence computers to augment motor and language function. Significant behavior problems may substantially interfere with the development of a child with CP; their early identification and management are important, and the assistance of a psychologist or psychiatrist may be necessary. Learning and attention deficit disorders and mental retardation are assessed and managed by a psychologist and educator. Strabismus, nystagmus, and optic atrophy are common in children with CP; an ophthalmologist should be included in the initial assessment. Lower urinary tract dysfunction should receive prompt assessment and treatment.

Bibliography

Mitochondrial encephalomyopathies are a heterogeneous group of clinical syndromes caused by genetic lesions that impair energy production through oxidative phosphorylation. The signs and symptoms of these disorders reflect the vulnerability of the nervous system, muscles, and other organs to energy deficiency. Signs of brain and muscle dysfunction (seizures, weakness, ptosis, external ophthalmoplegia, psychomotor regression, hearing loss, movement disorders, and ataxia) in association with lactic acidosis are prominent features of mitochondrial disorders. Cardiomyopathy and diabetes mellitus can also result from mitochondrial disorders.

Children with mitochondrial disorders often have multifocal signs that are intermittent or relapsing–remitting, often in association with intercurrent illness. Many of these disorders were described as clinical syndromes before their genetics were understood. Children with mitochondrial encephalomyopathy with lactic acidosis and stroke-like episodes (MELAS) present with developmental delay, weakness, and headaches, as well as focal signs that suggest a stroke. Brain imaging indicates that injury does not fit within the usual vascular territories. Children with myoclonic epilepsy with ragged red fibers (MERRF) present with myoclonus and myoclonic seizures as well as intermittent muscle weakness. The ragged red fibers referred to in the name of this disorder are clumps of abnormal mitochondria seen within muscle fibers in sections from a muscle biopsy stained with Gomori trichrome stain. NARP syndrome (neuropathy, ataxia, and retinitis pigmentosa), Kearns-Sayre syndrome (KSS; ptosis, ophthalmoplegia, heart block), Leigh disease (subacute necrotizing encephalomyelopathy), and Leber hereditary optic neuropathy (LHON) are also defined as relatively homogeneous clinical subgroups (Table 598-2). It is important to keep in mind that mitochondrial disorders can be difficult to diagnose. They often present with novel combinations of signs and symptoms as a consequence of high mutation rates for mitochondrial DNA (mtDNA), and the severity of disease varies from person to person.

Mitochondrial diseases can be caused by mutations of nuclear DNA (nDNA) or mtDNA (see Chapters 80, 86, and 87). Oxidative phosphorylation in the respiratory chain is mediated by 4 intramitochondrial enzyme complexes (complexes I-IV) and 2 mobile electron carriers (coenzyme Q and cytochrome c) that create an electrochemical proton gradient utilized by complex V (adenosine triphosphate [ATP] synthase) to create the ATP required for normal cellular function. The maintenance of oxidative phosphorylation requires coordinated regulation of nuclear DNA and mtDNA genes. Human mtDNA is a small (16.6 kb), circular, double-stranded molecule that has been completely sequenced and encodes 37 genes including 13 structural proteins, all of which are subunits of the respiratory chain complexes, as well as 2 ribosomal RNAs and 22 transfer RNAs (tRNAs) needed for translation. The nuclear DNA is responsible for synthesizing approximately 70 subunits, transporting them to the mitochondria via chaperone proteins, ensuring their passage across the inner mitochondrial membrane, and coordinating their correct processing and assembly. Diseases of mitochondrial oxidative phosphorylation can be divided into 3 groups: (1) defects of mtDNA, (2) defects of nDNA, and (3) defects of communication between the nuclear and mitochondrial genome. mtDNA is distinct from nDNA for the following 4 reasons: (1) its genetic code differs from nDNA, (2) it is tightly packed with information because it contains no introns, (3) it is subject to spontaneous mutations at a higher rate than nDNA, (4) it has less efficient repair mechanisms.

Inheritance of mutations present on mtDNA is nonmendelian and can be complex. At fertilization, mtDNA is present in hundreds or thousands of copies per cell and is transmitted by maternal inheritance from her oocyte to all her children, but only her daughters can pass it on to their children. Through the process called heteroplasmy or threshold effect, mtDNA containing mutations can be distributed unequally between cells in specific tissues. Some cells receive few or no mutant genomes (normal or wild-type homoplasmy), whereas

others receive a mixed population of mutant and wild-type mtDNAs (heteroplasy), and still others receive primarily or exclusively mutant genomes (mutant homoplasy). The important implications of maternal inheritance and heteroplasy are as follows: (1) inheritance of the disease is maternal, but both sexes are equally affected; (2) phenotypic expression of an mtDNA mutation depends on the relative proportions of mutant and wild-type genomes, with a minimum critical number of mutant genomes required for expression (threshold effect); (3) at cell division, the proportional distribution may shift between daughter cells (mitotic segregation), leading to a corresponding phenotypic change; and (4) subsequent generations are affected at a higher rate than in autosomal dominant diseases. The critical number of mutant mtDNAs required for the threshold effect may vary, depending on the vulnerability of the tissue to impairments of oxidative metabolism as well as on the vulnerability of the same tissue over time that may increase with aging. In contrast to maternal inherited disorders caused by mutations in mtDNA, diseases resulting from defects in nDNA follow mendelian inheritance. Mitochondrial diseases caused by defects in nDNA include defects in substrate transport (plasmalemmal carnitine transporter, carnitine palmityltransferases I and II, carnitine acylcarnitine translocase defects), defects in substrate oxidation (pyruvate dehydrogenase complex, pyruvate carboxylase, mitochondrial fatty acid oxidation defects), defects in the Krebs cycle (α-ketoglutarate dehydrogenase, fumarase, aconitate defects), and defects in the respiratory chain (complexes I-V), including defects of oxidation/phosphorylation coupling (Luft syndrome), and defects in mitochondrial protein transport.

Diseases caused by defects in mtDNA can be divided into those associated with point mutations that are maternally inherited (e.g., LHON, MELAS, MERRF, and NARP syndromes) and those caused by deletions or duplications of mtDNA that reflect altered communication between the nucleus and the mitochondria (KSS; Pearson syndrome, a rare severe encephalopathy with anemia and pancreatic dysfunction; and progressive external ophthalmoplegia). These disorders can be inherited by sporadic, autosomal dominant or recessive mechanisms and mutations in multiple genes, including mitochondrial mtDNA polymerase γ catalytic subunit (POLG), have been identified. POLG mutations have also been identified in patients with Alpers-Huttenlocher syndrome, which causes a refractory seizure disorder and hepatic failure as well as autosomal dominant and recessive progressive external ophthalmoplegia, childhood myocerebrohepatopathy spectrum disorders, myoclonic epilepsy, and ataxia syn- drome, and POLG-related ataxia neuropathy spectrum disorders. Other genes that regulate the supply of nucleotides for mtDNA synthesis are associated with severe encephalopathy and liver disease, and new disorders are being identified that result from defects in the inter- actions between mitochondria and their milieu in the cell.

MITOCHONDRIAL MYOPATHY, ENCEPHALOPATHY, LACTIC ACIDOSIS, AND STROKELIKE EPISODES

Children with MELAS may be normal for the 1st several yr, but they gradually display delayed motor and cognitive development and short stature. The clinical syndrome is characterized by (1) recurrent stroke-like episodes of hemiparesis or other focal neurologic signs with lesions most commonly seen in the posterior temporal, parietal, and occipital lobes (CT or MRI evidence of focal brain abnormalities); (2) lactic acidosis, ragged red fibers (RRF), or both; and (3) at least 2 of the following: focal or generalized seizures, dementia, recurrent migraine headaches, and vomiting. In 1 series, onset was before age 15 yr in 62% of patients, and hemianopia or cortical blindness was the most common manifestation. Cerebrospinal fluid protein is often increased. The MELAS 3243 mutation on mtDNA is the most common mutation to produce MELAS and can also be associated with different combinations of exercise intolerance, myopathy, ophthalmoplegia, pigmentary retinopathy, hypertrophic or dilated cardiomyopathy, cardiac conduction defects, deafness, endocrinopathy (diabetes mellitus), and proximal renal tubular dysfunction. A number of other mutations have been reported, and 2 patients have been described with bilateral rolandic lesions and epilepsy partialis continua associated with mtDNA mutations at 10158T>C and 10191T>C. MELAS is a progressive disorder that has been reported in siblings. However, most maternal relatives of MELAS patients are mildly affected or unaffected. MELAS is punctuated with episodes of stroke leading to dementia (see Chapter 611.4).

Regional cerebral hypoperfusion can be detected by single-photon emission CT studies and MR spectroscopy can detect focal areas of lactic acidosis in the brain. Neuropathology may show cortical atrophy with infarct-like lesions in both cortical and subcortical structures, basal ganglia calcifications, and ventricular dilation. Muscle biopsy specimens usually show RRF. Mitochondrial accumulations and abnormalities have been shown in smooth muscle cells of intramuscular vessels and of brain arteries and in the epithelial cells and blood vessels of the choroid plexus, producing a mitochondrial angiopathy. Muscle biochemistry shows complex I deficiency in many cases; however, multiple defects have also been documented involving complexes I, III, and IV. Targeted molecular testing for specific mutations or sequence analysis and mutation scanning are generally used to make a diagnosis of MELAS when clinical evaluation suggests the diagnosis. Because the number of mutant genomes is lower in muscle than in muscle, muscle is the preferable tissue for examination. Inheritance is maternal, and there is a highly specific, although not exclusive, point mutation at nt 3243 in the tRNA<sup>Leu(UUR)</sup> gene of mtDNA in approximately 80% of patients. An additional 7.5% have a point mutation at nt 3271 in the tRNA<sup>Leu(UUR)</sup> gene. A third mutation has been identified at nt 3252 in the tRNA<sup>Leu(UUR)</sup> gene. The prognosis in patients with the full syndrome is poor. Therapeutic trials reporting some benefit have included corticosteroids, coenzyme Q10, nicotinamide, carnitine, creatine, riboflavin and various combinations of these; t-arginine and preclinical studies reported some success with resveratrol.

MYOCLONUS EPILEPSY AND RAGGED RED FIBERS

MERRF syndrome is characterized by progressive myoclonic epilepsy, mitochondrial myopathy, and cerebellar ataxia with dysarthria and nystagmus. Onset may be in childhood or in adult life, and the course may be slowly progressive or rapidly downhill. Other features include dementia, sensorineural hearing loss, optic atrophy, peripheral neuropathy, and spasticity. Because some patients have abnormalities of deep sensation and pes cavus, the condition may be confused with Friedreich ataxia. A significant number of patients have a positive family history and short stature. This condition is maternally inherited.

Pathologic findings include elevated serum lactate concentrations, RRF on muscle biopsy, and marked neuronal loss and gliosis affecting, in particular, the dentate nucleus and inferior olivary complex with some dropout of Purkinje cells and neurons of the red nucleus. Pallor of the posterior columns of the spinal cord and degeneration of the gracile and cuneate nuclei occur. Muscle biochemistry has shown variable defects of complex III, complexes II and IV, complexes I and IV, or complex IV alone. More than 80% of cases are caused by a heteroplasmic G to A point mutation at nt 8344 of the tRNA<sup>Ser</sup> gene of mtDNA. Additional patients have been reported with a T to C mutation at nt 8356 in the tRNA<sup>Ser</sup> gene. Targeted mutation analysis or mutation analysis after sequencing of the mitochondrial genome is used to diagnosis MERRF.

There is no specific therapy, although coenzyme Q10 appeared to be beneficial in a mother and daughter with the MERRF mutation. The anticonvulsant levetiracetam is reported to help reduce myoclonus and myoclonic seizures in this disorder.

NEUROPATHY, ATAXIA, AND RETINITIS PIGMENTOSA SYNDROME

This maternally inherited disorder presents with either Leigh syn- drome or with neurogenic weakness and NARP syndrome, as well as seizures. It is caused by a point mutation at nt 8993 within the ATPase subunit 6 gene. The severity of the disease presentation appears to have close correlation with the percentage of mutant mtDNA in leukocytes.
Two clinical patterns are seen in patients with NARP syndrome: (1) neuropathy, ataxia, retinitis pigmentosa, dementia, and ataxia, and (2) severe infantile encephalopathy resembling Leigh syndrome with lesions in the basal ganglia on MRI.

**LEBER HEREDITARY OPTIC NEUROPATHY**

LHON is characterized by onset usually between the ages of 18 and 30 yr of acute or subacute visual loss caused by severe bilateral optic atrophy, although children as young as 5 yr have been reported to have LHON. Three mtDNA mutations account for most cases of LHON and at least 85% of patients are young men. An X-linked factor may modulate the expression of the mtDNA point mutation. The classic ophthalmologic features include circumpapillary telangiectatic microangiopathy and pseudodema of the optic disc. Variable features may include cerebellar ataxia, hyperreflexia, Babinski sign, psychiatric symptoms, peripheral neuropathy, or cardiac conduction abnormalities (preexcitation syndrome). Some cases are associated with widespread white matter lesions as seen with multiple sclerosis. Lactic acidosis and RRF tend to be conspicuously absent in LHON. More than 11 mtDNA point mutations have been described, including a usually homoplasmic G to A transition at nt 11,778 of the ND4 subunit gene of complex I. The latter leads to replacement of a highly conserved arginine residue by histidine at the 340th amino acid and accounts for 50-70% of cases in Europe and more than 90% of cases in Japan. Certain LHON pedigrees with other point mutations are associated with complex neurologic disorders and may have features in common with MELAS syndrome and with infantile bilateral striatal necrosis. One family has been reported with pediatric onset of progressive generalized dystonia with bilateral striatal necrosis associated with a homoplasmic G14459A mutation in the mtDNA ND6 gene, which is also associated with LHON alone and LHON with dystonia.

**KEARNS-SAYRE SYNDROME**

KSS is a characteristic multiorgan disorder involving external ophthalmoplegia, heart block, and retinitis pigmentosa with onset before age 20 yr caused by single deletions in mtDNA. There must also be at least 1 of the following: heart block, cerebellar syndrome, or cerebrosplinal fluid protein >100 mg/dL. Other nonspecific but common features include dementia, sensorineural hearing loss, and multiple endocrine abnormalities, including short stature, diabetes mellitus, and hyperparathyroidism. The prognosis is guarded, despite placement of a pacemaker, and progressively downhill, with death resulting by the 3rd or 4th decade. Unusual clinical presentations can include renal tubular acidosis and Lowe syndrome. There are also a few overlap cases of children with KSS and stroke-like episodes. Muscle biopsy shows RRF and variable cytochrome c oxidase (COX)-negative fibers. Most patients have mtDNA deletions, and some have duplications. These may be new mutations accounting for the generally sporadic nature of KSS. A few pedigrees have shown autosomal dominant transmission. Patients should be monitored closely for endocrine abnormalities, which can be treated. Coenzyme Q is reported anecdotally to have some beneficial effect; a positive effect of folinic acid for low folate levels also is reported. A report of positive effects of a cochlear implant for deafness is also reported.

Sporadic progressive external ophthalmoplegia with ragged red fibers is a clinically benign condition characterized by adolescent or young adult—onset ophthalmoplegia, ptosis, and proximal limb girdle weakness. It is slowly progressive and compatible with a relatively normal life. The muscle biopsy material demonstrates RRF and COX-negative fibers. Approximately 50% of patients with progressive external ophthalmoplegia have mtDNA deletions, and there is no family history.

**REVERSIBLE INFANTILE CYTOCHROME C OXIDASE DEFICIENCY MYOPATHY**

Mutations in mtDNA are also responsible for a reversible form of severe neumuscular weakness and hypotonia in infants that is the result of a maternally inherited homoplasmic m.14674T>C mt-tRNA\(^{\text{Glu}}\) mutation associated with a deficiency of COX. Affected children present within the 1st few wk of life with hypotonia, severe muscle weakness, and very elevated serum lactate levels, and they often require mechanical ventilation. However, feeding and psychomotor development are not affected. Muscle biopsies taken from these children in the neonatal period show RRF and deficient COX activity, but these findings disappeared within 5-20 mo when the infants recovered spontaneously. It is difficult to distinguish these infants from those with lethal mitochondrial disorders without waiting for them to improve. The mechanism for this recovery is not established, but it may reflect a developmental switch in mitochondrial RNAs later in infancy. This reversible disorder is observed only in COX deficiency associated with the 14674T>C mt-tRNA\(^{\text{Glu}}\) mutation, so it is suggested that infants with this type of severe weakness in the neonatal period be tested for this mutation to help with prognosis.

**LEIGH DISEASE (SUBACUTE NECROTIZING ENCEPHALOMYOPATHY)**

Leigh disease is a progressive degenerative disorder presenting in infancy with feeding and swallowing problems, vomiting, and failure to thrive associated with lactic acidosis and lesions seen in the brainstem and/or basal ganglia on MRI (Table 598-3). There are several genetically determined causes of Leigh disease that result from nuclear DNA mutations in genes that code for components of the respiratory chain: pyruvate dehydrogenase complex deficiency, complex I or II deficiency, complex IV (COX) deficiency, complex V (ATPase) deficiency, and deficiency of coenzyme Q10. These defects may occur sporadically or be inherited by autosomal recessive transmission, as in the case of COX deficiency; by X-linked transmission, as in the case of pyruvate dehydrogenase E\(_2\) deficiency; or by maternal transmission, as in complex V (ATPase 6 nt 8993 mutation) deficiency. Approximately 30% of cases are caused by mutations in mtDNA. Delayed motor and language milestones may be evident, and generalized seizures, weakness, hypotonia, ataxia, tremor, pyramidal signs, and nystagmus are prominent findings. Intermittent respirations with associated sighing or sobbing are characteristic and suggest brainstem dysfunction. Some patients have external ophthalmoplegia, ptosis, retinitis pigmentosa, optic atrophy, and decreased visual acuity. Abnormal results on CT or MRI scan consist of bilaterally symmetric areas of low attenuation in the basal ganglia and brainstem as well as elevated lactate acid on MR spectroscopy (Fig. 598-3). Pathologic changes consist of focal symmetric areas of necrosis in the thalamus, basal ganglia, tegmental gray matter, periventricular and periaqueductal regions of the brainstem, and posterior columns of the spinal cord. Macroscopically, these spongiform lesions show cystic cavitation with neuronal loss, demyelination, and vascular proliferation. Elevations in serum lactate levels are characteristic and hypertrophic cardiomyopathy, hepatic failure and renal tubular dysfunction can occur. The overall outlook is poor, but a few patients experience prolonged periods of remission. There is no definitive treatment for the underlying disorder, but a range of vitamins including riboflavin, thiamine, and coenzyme Q are often given to try to improve mitochondrial function. Biotin, creatine, succinate, and idebenone, as well as a high-fat diet have also been used, but phenobarbital and valproic acid should be avoided because of their inhibitory effect on the mitochondrial respiratory chain.

**REYE SYNDROME**

This encephalopathy, which has become uncommon, is associated with pathologic features characterized by fatty degeneration of the viscera (microvesicular steatosis) and mitochondrial abnormalities and biochemical features consistent with a disturbance of mitochondrial metabolism (see Chapter 361).

Recurrent Reye-like syndrome is encountered in children with genetic defects of fatty acid oxidation, such as deficiencies of the plasmalemmal carnitine transporter, carnitine palmityltransferases I and II, carnitine acylcarnitine translocase, medium- and long-chain acyl-coenzyme A dehydrogenase, multiple acyl-coenzyme A dehydrogenase, and long-chain L-3 hydroxyacyl-coenzyme A dehydrogenase or trifunctional protein. These disorders are manifested by recurrent hypoglycemic and hypoketotic encephalopathy, and they are inherited...

### 598.3 Other Encephalopathies

**Michael V. Johnston**

#### HIV ENCEPHALOPATHY

Encephalopathy is an uncommon and common manifestation in infants and children with HIV infection (see Chapter 276).

#### LEAD ENCEPHALOPATHY

See Chapter 721.

#### BURN ENCEPHALOPATHY

An encephalopathy develops in approximately 5% of children with significant burns in the 1st several wk of hospitalization (see Chapter 75). There is no single cause of burn encephalopathy but rather a combination of factors that include anoxia (smoke inhalation, carbon monoxide poisoning, laryngospasm), electrolyte abnormalities, bacte- remia and sepsis, cortical vein thrombosis, a concomitant head injury, cerebral edema, drug reactions, and emotional distress. Seizures are the most common clinical manifestation of burn encephalopathy, but altered states of consciousness, hallucinations, and coma may also occur. Management of burn encephalopathy is directed to a search for the underlying cause and treatment of hypoxemia, seizures, specific electrolyte abnormalities, or cerebral edema. The prognosis for complete neurologic recovery is generally excellent, particularly if seizures are the primary abnormality.

#### HYPERTENSIVE ENCEPHALOPATHY

Hypertensive encephalopathy is most commonly associated with renal disease in children, including acute glomerulonephritis, chronic pyelo- nephritis, and end-stage renal disease (see Chapters 445 and 535). In some cases, hypertensive encephalopathy is the initial manifestation of underlying renal disease. Marked systemic hypertension produces vasconstriction of the cerebral vessels, which leads to vascular permeability, causing areas of focal cerebral edema and hemorrhage. The onset may be acute, with seizures and coma, or more indolent, with headache, drowsiness and lethargy, nausea and vomiting, blurred vision, transient cortical blindness, and hemiparesis. Examination of the eye grounds may be nondiagnostic in children, but papilledema and retinal hemorrhages may occur. MRI often shows increased signal intensity in the occipital lobes on T2-weighted images, which is known as **posterior reversible leukoencephalopathy** (PRES) and may be confused with cerebral infarctions. These high signal areas may appear in other regions of the brain as well. PRES may also be seen in children without hypertension. In all circumstances, PRES manifests with generalized motor seizures, headache, mental status changes, and visual disturbances. CT may be normal in PRES; MRI is the study of choice. Treatment is directed at restoration of a normotensive state and control of seizures with appropriate anticonvulsants.

#### RADIATION ENCEPHALOPATHY

Acute radiation encephalopathy is most likely to develop in young patients who have received large daily doses of radiation. Excessive radiation injures vessel endothelium, resulting in enhanced vascular permeability, cerebral edema, and numerous hemorrhages. The child may suddenly become irritable and lethargic, complain of headache, or present with focal neurologic signs and seizures. Patients occasion- ally develop hemiparesis as the result of an infarct secondary to vascular occlusion of the cerebral vessels. Steroids are often beneficial in reducing the cerebral edema and reversing the neurologic signs. Late- radiation encephalopathy is characterized by headaches and slowly progressive focal neurologic signs, including hemiparesis and seizures. Exposure of the brain to radiation for treatment of childhood cancer increases the risk of later cerebrovascular disease, including stroke, moyamoya disease, aneurysm, vascular malformations, mineralizing microangiopathy, and stroke-like migraines. Some children with acute lymphocytic leukemia treated with a combination of intrathecal meth- otrexate and cranial irradiation develop neurologic signs months or years later; signs consist of increasing lethargy, loss of cognitive abili- ties, dementia, and focal neurologic signs and seizures (see Chapter 494). The CT scan shows calcifications in the white matter, and the postmortem examination demonstrates a necrotizing encephalopathy. This devastating complication of the treatment of leukemia has prompted re-evaluation and reduction in the use of cranial radiation in the treatment of these children.

#### ACUTE NECROTIZING ENCEPHALOPATHY

Acute necrotizing encephalopathy is a rare, severe encephalopathy seen more commonly in Asian countries. It is thought to be triggered by a viral infection (influenza, HHV-6) in a genetically susceptible host. Table 598-4 lists the diagnostic criteria. The elevation of hepatic enzymes without hyperammonemia is a unique feature. A familial or recurrent form is associated with mutations in the **RANBP2** gene and is designated **ANE1**. MRI finding are characterized by symmetric lesions that must be present in the thalami (Fig. 598-4). The prognosis is usually poor, however some patients have responded to steroids and intravenous immunoglobulin (IVIG).

**Cystic Leukoencephalopathy**

An autosomal recessive disorder caused by mutations of RNASET2 proteins produces a brain MRI study that closely resembles congenital cytomegalovirus infection. Cystic leukoencephalopathy is manifest as a static encephalopathy without megalencephaly.

Bibliography is available at Expert Consult.
Bibliography

Bibliography

Autoimmune encephalitis comprises an expanding group of clinical syndromes that can occur at all ages (<1 yr to adult) but preferentially affect younger adults and children (Table 598-5). These disorders associate with antibodies against neuronal cell surface proteins and synaptic receptors involved in synaptic transmission, plasticity, or neuronal excitability. The syndromes vary according to the associated antibody with phenotypes that resemble those in which the function of the target antigen is pharmacologically or genetically modified.

Most of these disorders are severe and potentially fatal but patients frequently respond to immunotherapy with good outcomes. Moreover, because of the broad spectrum of symptoms—including alterations of behavior, psychosis, catatonia, memory deficits, seizures, abnormal movements, and autonomic dysregulation—patients usually require a multidisciplinary treatment approach often in an intensive care unit.

The identification of these disorders provides a definitive diagnosis to many cases of encephalitis previously considered idiopathic, infectious, or postinfectious, although no causative agents were found. Because the etiology and pathogenic mechanisms were unknown, some of these disorders were previously defined with descriptive terms. More than half of cases under the ill-defined term “encephalitis lethargica” and some cases of “choreoathetosis post–herpes simplex encephalitis” are known to be anti–N-methyl-D-aspartate receptor (NMDAR) encephalitis.

The mechanisms that trigger the production of the antibodies are unknown. In a small subgroup of adolescent or young adult patients, the presence of a tumor that expresses the target neuronal antigen likely contributes in triggering the immune response. In addition, the high prevalence of prodromal viral-like symptoms has suggested that nonspecific viral infections may contribute to breaking immune tolerance and increase the permeability of the blood–brain barrier to antibodies. Nonetheless in many of these disorders the blood–brain barrier appears intact and there is evidence that the autoantibodies are

Encephalopathies

**ANTI-N-METHYL-D-ASPARTATE RECEPTOR ENCEPHALITIS**

In this disorder, the antibodies target the NR1 subunit of the NMDA receptor. The exact frequency of this syndrome is unknown but it is considered the second most common cause of autoimmune encephalitis after acute disseminated encephalomyelitis in children and adolescents. Overall, the disorder predominates in females (80%), although in patients younger than 12 yr the frequency of males is higher (40%). The resulting syndrome is highly predictable and usually evolves in stages. In teenagers and young adults, the disorder usually presents with prominent psychiatric manifestations that may include rapidly progressive anxiety, agitation, delusional thoughts, bizarre behavior, labile affect, mood disturbances (mania), catatonic features, memory deficit, language disintegration, aggression, and insomnia or other sleep disturbances. In many cases, these symptoms had been preceded by a few days of prodromal headache, fever or viral-like symptoms. As a result of this symptom presentation, patients are often misdiagnosed with new-onset psychosis or a primary psychiatric disorder. However, in a few days or weeks, additional symptoms occur, including a decreased level of consciousness, seizures (including status epilepticus), limb or oral dyskinesias, choreoathetoid movements, and autonomic instability which usually includes tachycardia, bradycardia, fluctuations of blood pressure, hypoventilation, hyperthermia and sialorrhea. In rare instances, bradycardia and cardiac pauses occur, at times requiring the transient use of a pacemaker. The disorder also occurs in toddlers and infants (the youngest patient identified to date was 6 mo old), and although the evolution of the syndrome is similar to that of adults, young patients more frequently present with motor or complex seizures and movement disorders. Because of their age, the psychiatric–behavioral features may be missed. In this young age group, behavior changes include irritability, new-onset temper tantrums, agitation, aggression, reduced speech, mutism, and autistic-like regression. Moreover, compared with adults some children also develop cerebellar ataxia and hemiparesis; in contrast, autonomic dysfunction is usually milder and less severe in children. There is often an abrupt on–off phenomenon in alterations of responsiveness or level of consciousness.

Brain MRI is abnormal in approximately 35% of cases, usually showing nonspecific cortical and subcortical T2-fluid-attenuated inversion recovery (FLAIR) signal abnormalities, sometimes with transient cortical or meningeal enhancement; nonspecific white matter abnormalities are common. Lesions may also involve the spinal cord producing symptoms of myelitis. The cerebrospinal fluid (CSF) is initially abnormal in approximately 80% of cases, showing moderate lymphocytic pleocytosis and less frequently increased protein synthesis and oligoclonal bands. The electroencephalogram (EEG) is abnormal in virtually all patients, and usually shows focal or diffuse slow activity in the delta and theta range, which does not correlate with abnormal movements. In addition, many patients develop epileptic activity, requiring video-monitoring for adequate clinical management. A characteristic EEG pattern called “extreme delta brush” characterized by beta-delta complexes occurs in 30% of adults and has been described in children (Fig. 598-5).

The diagnosis of the disorder is established by demonstrating NMDAR antibodies in CSF or serum. The sensitivity is higher in CSF compared with serum (100% vs 85%), and the levels of antibodies in CSF appear to correlate better with outcome. Antibodies may remain detectable, albeit at lower titers, after patients recover.

The presence of an underlying tumor, mostly teratomas, is age and sex dependent. Whereas 40% of females older than 12 yr have an underlying teratoma of the ovary, less than 6% of females younger than 12 yr have a tumor. In young boys with anti-NMDAR encephalitis, the presence of an underlying tumor is exceptional; in young adults, the presence of a testicular teratoma is also rare (<15% of cases). In children, MRI of abdomen and pelvis and abdominal and testicular ultrasound are the preferred tumor screening tests.

In a small number of patients, anti-NMDAR encephalitis occurs simultaneously or after infections with a variety of pathogens, including *Mycoplasma pneumoniae*, human herpes simplex viruses 1 and 6 (HSV), enterovirus, and influenza. A pathogenic link with most of these infections has not established; there is evidence that some patients with HSV encephalitis develop antibodies against the NR1 subunit of the NMDAR. These patients may progress to develop relapsing neurologic symptoms post-HSV encephalitis. In a subgroup of patients with noninfectious relapsing neurologic symptoms post-HSV encephalitis, or “choreoathetosis post-HSV encephalitis,” the disorder is in fact anti-NMDAR encephalitis (see Videos 598-1, 598-2, and 598-3).

Although no prospective clinical trials have been done, there is evidence that tumor removal, when appropriate, and prompt immunotherapy improve outcome. Most children receive first-line immunotherapies, including corticosteroids, IVIG, or plasma exchange. However, because these treatments fail in almost 50% of patients, and with an increasing number of reports showing that rituximab can be effective, this treatment is increasingly being used in combination with IVIG and steroids, or after first-line immunotherapies. Cyclophosphamide can be effective when there has been no response to these treatments.

Although anti-NMDAR encephalitis has a mortality rate of 7%, approximately 80% of patients have substantial or full recovery. Recovery is usually slow and can take as long as 2 yr after symptom onset. The last symptoms to improve are social interactions, and language and executive functions. Relapses occur in approximately 15% of patients; they can develop as partial syndromes, are usually milder than the initial episode and respond equally to immunotherapy. Initial comprehensive immunotherapy appears to prevent or reduce the number of relapses. The efficacy of chronic immunosuppression with drugs such as azathioprine or mycophenolate mofetil in preventing relapses is unknown.

The differential diagnosis of anti-NMDAR encephalitis is extensive and varies according to the stage of the disease (Table 598-6). The most frequently considered disorders are viral encephalitis, neuroleptic malignant syndrome, acute psychosis, and drug abuse.

**LIMBIC ENCEPHALITIS**

This disorder refers to an inflammatory process of the limbic system including, the medial temporal lobes, amygdala, and cingulate gyri. In adults, the most frequent immune-mediated limbic encephalitis occurs
<table>
<thead>
<tr>
<th>DISORDER</th>
<th>COMMENTS</th>
</tr>
</thead>
<tbody>
<tr>
<td>Viral encephalitis</td>
<td>Viral encephalitis is often suggested by the acute onset of symptoms, CSF pleocytosis, and hyperthermia. Most viral encephalitides (except rabies) occur with higher levels of CSF pleocytosis and protein concentration. Psychosis and dyskinesias are significantly less frequent in viral encephalitis than in anti-NMDAR encephalitis.</td>
</tr>
<tr>
<td>Relapsing post-herpes simplex virus encephalitis</td>
<td>Occurs ~4-6 wk after successful treatment of herpes simplex encephalitis. This may represent a true viral relapse of encephalitis (CSF PCR-positive, progression of necrotic MRI changes, response to acyclovir), or an autoimmune disorder (CSF PCR-negative, no new necrotic lesions on MRI, lack of response to acyclovir). In a proportion of the latter patients, the disorder is anti-NMDAR encephalitis.</td>
</tr>
<tr>
<td>New-onset psychosis</td>
<td>Because most patients with anti-NMDAR encephalitis present with psychosis, a primarily psychiatric disorder is frequently considered. As the disease evolves, the development of neurological symptoms usually reveals the diagnosis.</td>
</tr>
<tr>
<td>Drugs/toxins</td>
<td>The acute development of personality and behavioral changes, and symptoms suggesting involvement of dopaminergic pathways (rigidity, dystonia, orofacial movements) usually leads to a suspicion of drug abuse (e.g., ketamine, phencyclidine, among others). Carbon monoxide.</td>
</tr>
<tr>
<td>Neuroleptic malignant syndrome</td>
<td>The occurrence of altered level of consciousness, episodes of rigidity, hyperthermia, and autonomic instability often suggest NMS. In addition, some patients with anti-NMDAR encephalitis have elevated serum creatine kinase and rhabdomyolysis (in the absence of antipsychotic medication). The frequent use of neuroleptics to control the abnormal behavior adds further confusion between both syndromes. The presence of dyskinesias and catatonia suggest anti-NMDAR encephalitis.</td>
</tr>
<tr>
<td>Limbic encephalitis</td>
<td>Criteria of LE are well defined. Patients with LE do not have dyskinesias or central hypoventilation; the MRI usually shows abnormalities restricted to the medial temporal lobes, and the EEG findings (epileptic or slow activity) are largely restricted to the temporal lobes.</td>
</tr>
<tr>
<td>Encephalitis lethargica</td>
<td>This is an ill-defined entity, likely representing multiple disorders. Criteria include: acute or subacute encephalitis with at least 3 of the following: signs of basal ganglia involvement; oculogyric crises; opthalmoplegia; obsessive-compulsive behavior; akinetiform mutism; central respiratory irregularities; somnolence and/or sleep inversion. Approximately, 50% of patients categorized as encephalitis lethargica hyperkinetica have anti-NMDAR encephalitis.</td>
</tr>
<tr>
<td>Childhood disintegrative disorder/late-onset autism</td>
<td>Children with anti-NMDAR encephalitis often show cognitive regression, rapid loss of language function, autistic features, and seizures, suggesting a childhood disintegrative disorder. While the prognosis of CDD is poor, most patients with anti-NMDAR encephalitis respond to immunotherapy and have substantial clinical recovery.</td>
</tr>
<tr>
<td>Kleine-Levin syndrome</td>
<td>Symptoms of hypersomnia, compulsive hyperphagia, hypersexuality, apathy, and child-like behavior, which are typical components of Kleine-Levin syndrome, may occur transiently during the process of recovery of anti-NMDAR encephalitis, or as permanent sequelae.</td>
</tr>
<tr>
<td>Inborn errors of metabolism</td>
<td>Glutaric aciduria type I can present in previously asymptomatic patients as episodes of encephalopathy with dystonia, coinciding with an infection or febrile process. Several inborn errors of metabolism can also occur with acute or subacute encephalopathy with extrapyramidal signs, including 3-methylglutaconic aciduria, creatine transport deficiency, mitochondrial disorders (Leigh syndrome), Wilson, and Lesch-Nyhan syndromes. Pantetheinase kinase associated neurodegeneration, porphyria, and urea cycle defects should also be considered.</td>
</tr>
<tr>
<td>Monoamine neurotransmitter disorders</td>
<td>Deficiency of dopamine, serotonin or both can result in encephalopathy, epilepsy, and pyramidal and extrapyramidal symptoms. The diagnosis is established by examining the CSF for levels of these neurotransmitters.</td>
</tr>
<tr>
<td>Demyelinating disorders</td>
<td>Acute disseminated encephalomyelitis and neuromyelitis optica are immune-mediated inflammatory and demyelinating disorders of the central nervous system. These disorders should be considered in the differential diagnosis of multifocal neurologic abnormalities and encephalopathy in children. As with anti-NMDAR encephalitis these disorders may be preceded by an infection and can show pleocytosis. The diagnosis is suggested by the MRI findings. In NMO the presence of aquaporin 4 antibodies in serum or CSF is associated with relapses and poor prognosis.</td>
</tr>
<tr>
<td>CNS vasculitis</td>
<td>CNS vasculitis results in neurologic deficits and psychiatric manifestations. The diagnosis is established by angiography in large vessel angiitis, and brain biopsy in small vessel angiitis. In the latter, serum inflammatory markers (erythrocyte sedimentation rate, C-reactive protein, Complement 3, von Willebrand factor antigen) are usually elevated, and the MRI shows FLAIR/T2 abnormalities in the white and/or gray matter, not restricted to vascular territories with frequent leptomeningeal and/or local enhancement.</td>
</tr>
<tr>
<td>Systemic rheumatic disorders</td>
<td>Systemic lupus erythematosus and other rheumatic disorders can result in encephalopathy and multifocal neurologic and psychiatric manifestations. These disorders are usually suggested by the presence of signs and symptoms of involvement of systemic organs: skin, joints, kidneys, blood-forming cells, and blood vessels.</td>
</tr>

</table>

CDD, childhood disintegrative disorder; CNS, central nervous system; CSF, cerebrospinal fluid; EEG, electroencephalography; FLAIR, fluid-attenuated inversion recovery; LE, limbic encephalitis; MRI, magnetic resonance imaging; NMDAR, N-methyl-D-aspartate receptor; NMO, neuromyelitis optica; NMS, neuroleptic malignant syndrome; PCR, polymerase chain reaction.
in association with antibodies against proteins that were once thought to be voltage-gated potassium channels (VGKC), but which, in fact, target a secreted neuronal protein called leucine-rich glioma-inactivated 1 (LG1), and a protein called Caspr2 expressed in brain and juxtaparanodal regions of myelinated nerves. Patients with LG1 antibody associated limbic encephalitis often develop hypnoretinopia; in some patients the disorder is preceded by short-lasting episodes of distinctive dystonic or myoclonic-like movements, described as factocellular dystonic seizures, but with EEG features of tonic seizures. Patients with antibodies to Caspr2 usually develop Marfan syndrome, which includes encephalopathy, seizures, autonomic dysfunction, and neuromyotonia. How the clinical significance of antibodies called “VGKC-complex proteins” differs from LG1 and Caspr2 is unknown.

Other less frequent types of autoimmune limbic encephalitis in adults are paraneoplastic and may occur with antibodies against intracellular antigens (e.g., Hu, CRMP5, Ma2) or neuronal cell surface and synaptic proteins (e.g., AMPA, GABA$_B$, receptor, mGluR5). While the disorders associated with antibodies against intracellular antigens appear to be mediated by cytotoxic T-cell responses and are poorly responsive to treatment, those associated with antibodies to cell surface and synaptic antigens are likely mediated by the antibodies and treatment responsive.

In children, autoimmune or paraneoplastic limbic encephalitis is exceptional. Unfortunately, any type of encephalopathy resulting in seizures and alteration of memory and behavior is frequently labeled as “limbic encephalitis,” making data based on literature searches using the term “limbic encephalitis” unreliable. Fewer than 30 children with limbic encephalitis have been described in the English literature, some of them with antibodies against intracellular or cell surface antigens (Hu, Ma2, GAD, amphiphysin, GABA$_B$, and VGKC-complex proteins different from LG1 and Caspr2). In some cases an underlying tumor was identified and included, leukemia, ganglioneuroblastoma, neuroblastoma, and small-cell carcinoma of the ovary.

The Ophelia syndrome is a form of limbic encephalitis that occurs in association with Hodgkin’s lymphoma and predominantly affects young adults, teenagers or children. Some patients develop antibodies against mGluR5, a receptor involved in learning and memory; symptoms are usually responsive to chemotherapy.

**Hashimoto Encephalopathy**

Hashimoto encephalopathy is defined by the detection of thyroid peroxidase (TPO) antibodies in patients with acute or subacute encephalitis that responds to corticosteroids. Since almost 50% of patients have normal thyroid function and not all patients respond to steroids, the term “encephalopathy associated with autoimmune thyroid disease” is considered more accurate than the previous term “steroid-responsive encephalopathy associated with autoimmunity thyroiditis.” Clinical features are not specific and may include stroke-like symptoms, tremor, myoclonus, transient aphasia, sleep and behavior abnormalities, hallucinations, seizures, and ataxia. The CSF usually shows elevated protein level with less-frequent pleocytosis. EEG studies almost always are abnormal frequently showing generalized slowing. Brain MRI is usually normal, although it may show diffuse white matter abnormalities and meningeal enhancement that can resolve with steroid therapy. As TPO antibodies occur in approximately 10% of asymptomatic children (nonencephalopathic and most cases euthyroid), as well as in patients who have more relevant antibody-associated disorders, such as GABA$_B$, LG1, or NMDAR antibodies, TPO antibodies should be viewed as a marker of autoimmunity rather than a neurologic disease-specific or pathogenic antibody. Importantly the presence of TPO antibodies should not prevent testing for more relevant antibodies.

**Opsoclonus–Myoclonus and Other Brainstem–Cerebellar Encephalitides**

Opsoclonus-myoclonus occurs in infants, teenagers and adults, although it probably represents different diseases and pathogenic mechanisms. In infants, the syndrome usually develops in the 1st 2 yr of life (mean: 20 mo), and at least 50% of patients have an underlying neuroblastoma. The child often presents with irritability, ataxia, falling, myoclonus, tremor, and drooling. Additional symptoms may include refusal to walk or sit, speech problems, hypotonia, and the typical features of opsoclonus characterized by rapid, chaotic, multidirectional eye movements without saccadic intervals. Because opsoclonus may be absent at symptom presentation, patients may initially be diagnosed with acute cerebellitis or labyrinthisis. Typically CSF abnormalities suggest B-cell activation, and the presence of antibodies against neuronal proteins has been demonstrated in several studies, although the identification of a specific autoantigen has been elusive.

Immunosuppressive treatment, including corticosteroids, IVIG, rituximab, and cyclophosphamide often improves the abnormal eye movements, but residual behavioral, language, and cognitive problems persist in the majority of patients, often requiring special education. In addition, insomnia and abnormal response to pain are common. Relapses occur in 50% of the patients, usually as a result of an intercurrent infection or drug tapering. Delay in treatment appears to associate with a poorer neurologic outcome; therefore, in cases with neuroblastoma, removal of the tumor should not delay the start of immunotherapy.

In teenagers and young adults, opsoclonus–myoclonus and brainstem–cerebellar encephalitis without opsoclonus are often considered “idiopathic” or “postinfectious”; however, there is evidence that some of these patients have an underlying teratoma, usually in the ovaries. These patients do not harbor NMDAR antibodies, and compared with those with anti-NMDAR encephalitis are less likely to initially present with psychosis and behavioral changes, and rarely develop dyskinesias. Although these patients do not appear to have neuronal antibodies, the CSF often shows pleocytosis and elevated protein concentration. Identification of this subphenotype of opsoclonus–myoclonus is important because patients usually have full recovery after treatment with immunotherapy (corticosteroids, IVIG, and/or plasma exchange) and if present, removal of the ovarian teratoma. The prognosis of this disorder seems better than that of neuroblastoma-associated opsoclonus, or the paraneoplastic opsoclonus of older patients, usually related to breast, ovarian, or lung cancer.

**Bickerstaff Encephalitis**

This term is used to describe patients with subacute progressive ophthalmoplegia and ataxia in addition to drowsiness or hyperreflexia. Although this entity has been described more frequently in adults, children as young as 3 yr old have been identified. Most patients are treated with steroids, IVIG, and/or plasma exchange, and often have good outcome. Serum GQ1b immunoglobulin G antibodies are found in 66% of patients. Brain MRI abnormalities occur in 30% of the patients and usually include increased T2-signal abnormalities in the brainstem, thalamus, cerebellum, and sometimes cerebral white matter. Some patients develop hyponatremia and limb weakness, with predominant axonal involvement, overlapping with symptoms of the Miller-Fisher syndrome and the axonal subtype of the Guillain-Barré syndrome.

**Chronic Lymphocytic Inflammation With Pontine Perivascular Enhancement Responsive to Steroids**

This is a clinically and radiologically distinct pontine-predominant encephalomyelitis. To date fewer than 30 patients have been reported and two of them were children (13 and 16 yr). Patients usually present with episodic diplopia or facial paresthesias with subsequent development of symptoms of brainstem and occasionally spinal cord dysfunction. Brain MRI shows symmetric curvilinear gadolinium enhancement peering the pons and extending variably into the medulla, brachium pontis, cerebellum, midbrain and occasionally spinal cord. The clinical and radiological findings usually respond to high dose steroids but may worsen after the steroid taper, requiring chronic steroid or other immunosuppressive therapy. The differential diagnosis is extensive and includes infections, granulomatous disease, lymphoma or vasculitis. Biopsy studies may be needed to exclude these and other conditions.
AUTOIMMUNE ENCEPHALOPATHIES ASSOCIATED WITH EPILEPSY AND STATUS EPILEPTICUS

Rasmussen encephalitis is an inflammatory encephalopathy characterized by progressive refractory partial seizures, cognitive deterioration, and focal deficits that occur with gradual atrophy of 1 brain hemisphere. The disorder frequently presents in 6-8 yr old children, although adolescents and adults can be affected. The etiology is unknown and, therefore, multiple theories are proposed, including the presence of antibodies against the Glur3 subunit of the AMPA receptor and T-cell mediated mechanisms triggered by a viral infection. None of these mechanisms satisfactorily explains the unilateral brain involvement characteristic of the disorder. Treatment with high-dose steroids, plasma exchange, or IVIG can ameliorate symptoms in early stages of the disease. Rituximab and intraventricular γ-interferon have been effective in a few isolated cases. In a small series, patients treated with tacrolimus showed better outcomes of neurologic function and slower progression of cerebral hemiatrophy, but not improved seizure control. The only definitive treatment is functional hemispherectomy that consists in surgical disconnection of the affected hemisphere.

The discovery of treatment-responsive encephalitis associated with antibodies against cell surface or synaptic proteins has resumed the interest for a potential autoimmune basis of several devastating encephalopathies with refractory seizures. Some well-defined autoimmune encephalitis such as anti-NMDAR encephalitis can present in children with refractory seizures or status epilepticus. In these patients, the development over a short period of time of the characteristic spectrum of symptoms (altered behavior, orofacial dyskinesias, and autonomic dysfunction) and demonstration of NMDAR antibodies leads to the correct diagnosis and initiation of immunotherapy.

A devastating epileptic encephalopathy associated with fever named fever-induced refractory epileptic encephalopathy syndrome, among other terms, is suspected to be an infection-triggered autoimmune process because of its biphasic clinical course and the occasional finding of neuronal antibodies in a few patients. However, the lack of response to most treatments including immunotherapy, and the rare and inconsistent association to different types of antibodies cast doubts on an autoimmune pathogenesis. Other investigators suggest a genetic error in metabolism.

Antibodies to VGKC-complex proteins different from LGI1 and Caspr2 have been described in a few children with encephalitis with or without status epilepticus. Given that the target antigens are unknown and the response to immunotherapy is unpredictable, the significance of these antibodies is unclear.

OTHER SUSPECTED AUTOIMMUNE ENCEPHALITIDES

Demyelinating disorders, vasculitis of the CNS, and rheumatic diseases associate with autoimmune mechanisms can result in encephalitis. Rapid onset obesity with hypothalamic dysfunction, hypoventilation, and autonomic dysregulation (ROHHAD) usually affects children who had normal development until 2-4 yr of age and then develop rapid onset of hyperphagia, weight gain, and abnormal behavior (social disinhibition, irascibility, impulsivity, lethargy, outburst of euphoria and laughing, impaired concentration), followed by autonomic dysfunction (abnormal pupillary responses, thermal dysregulation, gastrointestinal dysmotility), and central hypoventilation. An autoimmune or paraneoplastic etiology of ROHHAD syndrome is supported by the frequent association to neural crest tumors, the identification in some patients of genetic factors predisposing to autoimmunity, and the finding of intrathecal oligoclonal bands and infiltrates of lymphocytes and histiocytes in the hypothalamus of some patients. Furthermore, responses to immunotherapy have been described in a few patients. A possible genetic origin is suggested because of the similarity of this syndrome with the congenital central hypoventilation syndrome (Ondine curse) related to a PHOX2B mutation, which presents in the neonatal period and also associates with autonomic problems (Hirschsprung disease) and neural crest tumors (see Chapter 418.2).

However, no mutations in PHOX2B and other candidate genes have been found in patients with ROHHAD.

The term basal ganglia encephalitis is used to describe patients with predominant or isolated involvement of the basal ganglia. These patients typically have abnormal movements and neuropsychiatric disease. Although these disorders probably have multiple etiologies, including metabolic, toxic, genetic, and infectious processes, an immune-mediated etiology has been postulated in some patients. There have been no clinical trials, but case reports and small controlled case series describe the potential benefit of immunotherapy. Antibodies against the dopamine-2 receptor have been identified in some of these patients as well as in patients with Sydenham chorea and Tourette syndrome.

Pseudomigraine syndrome with CSF pleocytosis (PMP) or headache with neurologic deficits and CSF lymphocytosis (HaNDL) is an ill-defined entity that predominantly affects young male adults with a family history of migraine, although adolescents can be affected. This syndrome is characterized by repeated episodes of severe headache with transient neurologic deficits, accompanied by aseptic CSF lymphocytosis and normal brain MRI. Patients frequently show high CSF opening pressure, elevated CSF protein concentration, and focal EEG slowing, which normalize after the episodes of headache. Because of the inflammatory characteristics of the CSF and the high prevalence of prodromal viral-like symptoms, an infectious-autoimmune mediated mechanism has been proposed. Other theories include spreading cortical depression and trigeminal-vascular activation.

An immune-mediated mechanism and trigeminal-vascular activation are also considered as possible mechanisms of ophthalmoplegic migraine, also named recurrent cranial neuralgia. This disorder predominantly affects young children and is characterized by recurrent bouts of head pain in addition to cranial nerves III, IV, and/or VI involvement. In contrast to PMP/HaNDL, CSF studies do not show pleocytosis, and in approximately 75% of cases, the MRI shows focal nerve thickening and contrast enhancement. Observational data suggest that treatment with steroids may be beneficial. In this syndrome, as well as in PMP/HaNDL, the differential diagnosis includes structural, neoplastic, traumatic, metabolic, and infectious disorders.

Bibliography

Neurodegenerative disorders of childhood encompass a large, heterogeneous group of diseases that result from specific genetic and biochemical defects, chronic viral infections, and varied unknown causes. Children with suspected neurodegenerative disorders were once subjected to brain and rectal (neural) biopsies, but with modern neuroimaging techniques and specific biochemical and molecular diagnostic tests, these invasive procedures are rarely necessary. The most important component of the diagnostic investigation continues to be a thorough history and physical examination. The hallmark of a neurodegenerative disease is *regression and progressive deterioration* of neurologic function with loss of speech, vision, hearing, or locomotion, often associated with seizures, feeding difficulties, and impairment of intellect. The age of onset, rate of progression, and principal
neurologic findings determine whether the disease affects primarily the white or the gray matter. Upper motor neuron signs and progressive spasticity are the hallmarks of white matter disorders; convulsions and intellectual and visual impairments that occur early in the disease course are the hallmarks of gray matter disorders. A precise history and intellectual and visual impairments that occur early in the disease course are the hallmarks of gray matter disorders. A precise history confirms regression of developmental milestones, and the neurologic examination localizes the process within the nervous system. Although the outcome of a neurodegenerative condition is usually fatal and available therapies are often limited in effect, it is important to make the correct diagnosis so that genetic counseling may be offered and prevention strategies can be implemented. Bone marrow transplantation and other novel therapies may prevent the progression of disease in certain individuals who are either presymptomatic or very early in their disease course. For all conditions in which the specific enzyme defect is known, prevention by prenatal diagnosis (chorionic villus sampling or amniocentesis) is possible. Carrier detection is also often possible by enzyme assay. Table 599-1 summarizes selected inherited neurodegenerative and metabolic disorders by their usual age of onset.

### 599.1 Sphingolipidoses

Jennifer M. Kwon

The sphingolipidoses are characterized by intracellular storage of lipid substrates resulting from defective catabolism of the sphingolipids comprising cellular membranes (Fig. 599-1). The sphingolipidoses are subclassified into 6 categories: Niemann-Pick disease, Gaucher disease, GM1 gangliosidosis, GM2 gangliosidosis, Krabbe disease, and metachromatic leukodystrophy. Niemann-Pick disease and Gaucher disease are discussed in Chapter 86.4.

### GANGLIOSIDOSIDOS

See also Chapter 86.4.

Gangliosides are glycosphingolipids, normal constituents of the neuronal and synaptic membranes. The basic structure of GM1 ganglioside consists of an oligosaccharide chain attached to a hydroxyl group of ceramide and sialic acid bound to galactose. The gangliosides are catabolized by sequential cleavage of the sugar molecules...
Part XXVII ◆ The Nervous System

Development is globally delayed, and generalized seizures are prominent. The phenotype is striking and shares many characteristics with Hurler syndrome. The facial features are coarse, the forehead is prominent, the nasal bridge is depressed, the tongue is large (macroglossia), and the gums are hypertrophied. Hepatosplenomegaly is present early in the course as a result of accumulation of foamy histiocytes, and kyphoscoliosis is evident because of anterior beaking of the vertebral bodies. The neurologic examination is dominated by apathy, progressive blindness, deafness, spastic quadriplegia, and decerebrate rigidity. A cherry-red spot in the macular region is visualized in approximately 50% of cases. The cherry-red spot is characterized by an opaque ring (sphingolipid-laden retinal ganglion cells) encircling the normal red fovea (Fig. 599-2). Children rarely survive beyond age 2-3 yr, and death may be from aspiration pneumonia.

Juvenile GM1 gangliosidosis has a delayed onset beginning about 1 yr of age. The initial symptoms consist of incoordination, weakness,
ataxia, and regression of language. Thereafter, convulsions, spasticity, decerebrate rigidity, and blindness are the major findings. Unlike the infantile type, this type is not usually marked by coarse facial features and hepatosplenomegaly. Radiographic examination of the lumbar vertebrae may show minor beaking. Children rarely survive beyond 10 yr of age. Adult GM\textsubscript{1} gangliosidosis is a slowly progressive disease consisting of spasticity, ataxia, dysarthria, and a gradual loss of cognitive function.

**GM\textsubscript{2} Gangliosidoses**

The GM\textsubscript{2} gangliosidoses are a heterogeneous group of autosomal recessive inherited disorders that consist of several subtypes, including Tay-Sachs disease (TSD), Sandhoff disease, juvenile GM\textsubscript{2} gangliosidosis, and adult GM\textsubscript{2} gangliosidosis. TSD is most prevalent in the Ashkenazi Jewish population and has an approximate carrier rate of 1 in 30 Jews in the United States. TSD is caused by mutations in the HEXA gene located on chromosome 1q23-q24. Affected infants appear normal until approximately 6 mo of age, except for a marked startle reaction to noise that is evident soon after birth. Affected children then begin to lag in developmental milestones and, by 1 yr of age, they lose the ability to stand, sit, and vocalize. Early hypotonia develops into progressive spasticity, and relentless deterioration follows, with convulsions, blindness, deafness, and cherry-red spots in almost all patients (see Fig. 599-2). Macrocephaly becomes apparent by 1 yr of age and results from the 200-300-fold normal content of GM\textsubscript{2} ganglioside deposited in the brain. Few children live beyond 3-4 yr of age, and death is usually associated with aspiration or bronchopneumonia. A deficiency of the isozyme hexosaminidase A is found in tissues of patients with TSD. Mass screening for prenatal diagnosis of TSD is a reliable and cost-effective method of prevention because the condition occurs most frequently in a defined population (Ashkenazi Jews). Targeted screening is responsible for the fact that currently, the rare children with TSD born in the United States are most commonly born to non-Jewish parents who are not routinely screened. An accurate and inexpensive carrier detection test is available (serum or leukocyte hexosaminidase A), and the disease can be reliably diagnosed by chorionic villus sampling in the 1st trimester of pregnancy in couples at risk (heterozygote parents).

**Sandhoff disease** is very similar to TSD in the mode of presentation, including progressive loss of motor and language milestones beginning at 6 mo of age. Seizures, cherry-red spots, macrocephaly, and doll-like facies are present in most patients; however, children with Sandhoff disease may also have splenomegaly. The visual evoked potentials (VEPs) are normal early in the course of Sandhoff disease and TSD, but become abnormal or absent as the disease progresses. The auditory brainstem responses show prolonged latencies. The diagnosis of Sandhoff disease is established by finding deficient levels of hexosaminidases A and B in serum and leukocytes. Children usually die by 3 yr of age. Sandhoff disease is caused by mutations in the HEXB gene located on chromosome 5q13.

**Juvenile GM\textsubscript{2} gangliosidosis** develops in mid-childhood, initially with clumsiness followed by ataxia. Signs of spasticity, athetosis, loss of language, and seizures gradually develop. Progressive visual loss is associated with optic atrophy, but cherry-red spots rarely occur in juvenile GM\textsubscript{2} gangliosidosis. A deficiency of hexosaminidase is variable (total deficiency to near normal) in these patients. Death occurs around 15 yr of age.

**Adult GM\textsubscript{2} gangliosidosis** is characterized by a myriad neurologic signs, including slowly progressive gait ataxia, spasticity, dystonia, proximal muscle atrophy, and dysarthria. Generally, visual acuity and intellectual function are unimpaired. Hexosaminidase A activity alone or hexosaminidases A and B activity is reduced significantly in the serum and leukocytes.

**Krabbe Disease (Globoid Cell Leukodystrophy)**

Krabbe disease (KD) is a rare autosomal recessive neurodegenerative disorder characterized by severe myelin loss and the presence of globoid bodies in the white matter. The gene for KD (GALC) is located on chromosome 14q24.3-q23.1. The disease results from a marked deficiency of the lysosomal enzyme galactocerebroside β-galactosidase. KD is a disorder of myelin destruction rather than abnormal myelin formation. Normally, myelination begins in the 3rd trimester, corresponding with a rapid increase of galactocerebroside β-galactosidase activity in the brain. In patients with KD, galactocerebroside cannot be metabolized during the normal turnover of myelin because of deficiency of galactocerebroside β-galactosidase. When galactocerebroside is injected into the brains of experimental animals, a globoid cell reaction ensues. It is postulated that a similar phenomenon occurs in humans; nonmetabolized galactocerebroside stimulates the formation of globoid cells that reflect the destruction of oligodendroglial cells. Because oligodendroglial cells are responsible for the elaboration of myelin, their loss results in myelin breakdown, thus producing additional galactocerebroside and causing a vicious circle of myelin destruction.

The symptoms of KD become evident in the 1st few mo of life and include excessive irritability and crying, unexplained episodes of hyperpyrexia, vomiting, and difficulty feeding. In the initial stage of KD, children are often treated for colic or milk allergy with frequent formula changes. Generalized seizures may appear early in the course of the disease. Alterations in body tone with rigidity and opisthotonus and visual inattentiveness as a result of optic atrophy become apparent as the disease progresses. In the later stages of the illness, blindness, deafness, absent deep-tendon reflexes, and decerebrate rigidity constitute the major physical findings. Most patients die by 2 yr of age. MRI and magnetic resonance spectroscopy are useful for evaluating the extent of demyelination in KD. Umbilical cord blood (stem cell) transplantation from unrelated donors in asymptomatic babies may favorably alter the natural history but will not help patients who already have neurologic symptoms.

**Late-onset KD** has been described beginning in childhood or adolescence. Patients present with optic atrophy and cortical blindness, and their condition may be confused with adrenoleukodystrophy. Slowly progressive gait disturbances, including spasticity and ataxia, are prominent. As with classic KD, globoid cells are abundant in the white matter, and leukocytes are deficient in galactocerebroside β-galactosidase. An examination of the cerebrospinal fluid shows an elevated protein content, and the nerve conduction velocities are markedly delayed as a result of segmental demyelination of the peripheral nerves. The VEPs decrease gradually in amplitude with no response in the late stages of the disease, and the auditory brainstem responses are characterized by the presence of only waves I and II. CT scans and MRI studies highlight the marked decrease in white matter, especially of the cerebellum and centrum semiovale, with sparing of the subcortical U fibers. Prenatal diagnosis is possible by the assay of galactocerebroside β-galactosidase activity in chorionic villi or in cultured amniotic fluid cells. Newborn screening may identify patients at risk for late onset disease.
Metachromatic Leukodystrophy

This disorder of myelin metabolism is inherited as an autosomal recessive trait and is characterized by a deficiency of arylsulfatase A activity. The ARSA gene is located on chromosome 22q13-13qter. The absence or deficiency of arylsulfatase A leads to accumulation of cerebroside sulfate within the myelin sheath of the central nervous system (CNS) and peripheral nervous system because of the inability to cleave sulfate from galactosyl-3-sulfate ceramide. The excessive cerebroside sulfate is thought to cause myelin breakdown and destruction of oligodendroglia. Prenatal diagnosis of metachromatic leukodystrophy (MLD) is made by assaying of arylsulfatase A activity in chorionic villi or cultured amniotic fluid cells. Cresyl violet applied to tissue specimens produces metachromatic staining of the sulfatide granules, giving the disease its name. Some individuals with low arylsulfatase A enzyme activity are clinically normal and have a pseudodeficiency state that can only be confirmed by additional genetic or biochemical tests. Those affected with MLD are generally classified according to age of onset: late infantile, juvenile, and adult.

**Late infantile MLD** begins with insidious onset of gait disturbances between 1 and 2 yr of age. The child initially appears awkward and frequently falls, but locomotion is gradually impaired significantly and support is required to walk. The extremities are hypotonic, and the deep-tendon reflexes are absent or diminished. Within the next several months, the child can no longer sit unsupported, and deterioration in intellectual function becomes apparent. The speech is slurred and dysarthric, and the child appears dull and apathetic. Visual fixation is diminished, nystagmus is present, and examination of the retina shows optic atrophy. Within 1 yr from the onset of the disease, the child is unable to sit unsupported, and progressive decorticate postures develop. Feeding and swallowing are impaired because of pseudobulbar palsies, and a feeding gastrostomy is required. Patients ultimately become stuporous and die of aspiration or bronchopneumonia by age 5-6 yr. Neurophysiologic evaluation shows slowing of peripheral nerve conduction velocities and progressive changes in the VEPs, auditory brainstem responses, and somatosensory evoked potentials. CT and MRI images of the brain indicate diffuse symmetric attenuation of the cerebral white matter, and examination of the cerebrospinal fluid shows an elevated protein content. Bone marrow transplantation is a promising experimental therapy for the management of late infantile MLD, and early trials of enzyme replacement are being conducted.

**Juvenile MLD** has many features in common with late infantile MLD, but the onset of symptoms is delayed to 5-10 yr of age. Deterioration in school performance and alterations in personality may herald the onset of the disease. This is followed by incoordination of gait, urinary incontinence, and dysarthria. Muscle tone becomes increased, and ataxia, dystonia, or tremor may be present. In the terminal stages, generalized tonic–clonic convulsions are prominent and are difficult to control. Patients rarely live beyond mid-adolescence.

**Adult MLD** occurs from the 2nd to 6th decade. Abnormalities in memory, psychiatric disturbances, and personality changes are prominent features. Slowly progressive neurologic signs, including spasticity, dystonia, optic atrophy, and generalized convulsions, lead eventually to a bedridden state characterized by decorticate postures and unresponsiveness.

*Note that all the NCL genes have the prefix CLN. The adult form (also called Kufs disease, with locus CLN4, caused by mutations in DNAJC5) is not well characterized and is not included in the table.

†Direct genetic testing is available for all.

‡Enzyme testing available.

The neuronal ceroid lipofuscinoses (NCLs) are a group of inherited, neurodegenerative, lysosomal storage disorders characterized by visual loss, progressive dementia, seizures, motor deterioration, and early death. The NCLs are so named because of the intracellular accumulation of fluorescent lipopigments, ceroid and lipofuscin. They comprise a genetically and phenotypically heterogeneous group of disorders (currently there are at least 9 NCL types) that have traditionally been subclassified by age of onset, among other clinical features. They differ from one another in the associated ultrastructural patterns of the inclusions as seen by electron microscopy. Evaluation of neuronal biopsies (either brain, rectal, conjunctival, or skin) was once required for diagnosis. With the advent of enzymatic and molecular testing methods, clinicians can make specific NCL diagnoses using less-invasive methods (Table 599-2).

**Infantile-type neuronal ceroid lipofuscinose (INCL, Haltia-Santavuori)** begins in the 1st yr of life with myoclonic seizures, intellectual deterioration, and blindness. Optic atrophy and brownish discoloration of the macula are evident on examination of the retina, and cerebellar ataxia is prominent. The electroretinogram typically shows small-amplitude or absent waveforms. Death occurs during childhood. The infantile form is caused by recessive mutations of the gene for the lysosomal enzyme palmitoyl-protein thioesterase-1 (PPT1) on chromosome 1p32. A number of cell types in INCL patients show characteristic intracellular fine granular osmiophilic deposits discernible by electron microscopy.
Bibliography

A subset of children with PPT1 enzyme deficiency has a much less-severe course with clinical features resembling those of the juvenile-onset NCL patients. Clinically, these variant INCL patients have a course that is often quite distinct from the typical, classic rapidly degenerating infantile form. Yet they have PPT1 deficiency and granular osmiophilic deposits on pathology. There is no clear CLN1 genotype that predicts severity of phenotype.

**Late infantile-type neuronal ceroid lipofuscinosis (LINCL, Jansky-Bielschowsky)** generally presents with myoclonic seizures beginning between 2 and 4 yr of age in a previously normal child. Dementia and ataxia are combined with a progressive loss of visual acuity and microcephaly. Examination of the retina shows marked attenuation of vessels, peripheral black bone spicule pigmented abnormalities, optic atrophy, and a subtle brown pigment in the macular region. The electroretinogram and VEP are abnormal early in the course of disease. The autofluorescent material is deposited in neurons, fibroblasts, and secretory cells. Electron microscopic examination of the storage material in skin or conjunctival biopsy material typically shows curvilinear profiles. LINCL can be caused by autosomal recessive mutations of several different genes: *CLN2*, which codes for a tripeptidyl peptidase-1 (TPP1) that is essential for the degradation of cholecystokinin-8, as well as the *CLN5, CLN6*, and *CLN8* genes that code for membrane proteins that have not been completely characterized. *CLN8* is also known as the locus of Northern epilepsy syndrome, which is often called progressive epilepsy with mental retardation.

**Juvenile type neuronal ceroid lipofuscinosis (JNCL, Spielmeyer-Vogt or Batten disease)** is the most common form of NCL disease and is generally caused by autosomal-recessive mutations in *CLN3*. (Patients who present clinically with INCL but have PPT1 or TPP1 deficiency are said to have variant INCL or LINCL, respectively.) Children affected with JNCL tend to develop normally for the 1st 5 yr of life. Their initial symptom is usually progressive visual loss and their retinal pigment changes often results in an initial diagnosis of retinitis pigmentosa. The funduscopic changes are similar to those for the late infantile type. After disease onset, there may be rapid decline with changes in cognition and personality, motor incoordination, and seizures. Myoclonic seizures are not as prominent as in LINCL, but parkinsonism can develop and impair ambulation. Patients die in their late twenties to early thirties. In JNCL caused by *CLN3*, the electron microscopy of tissues show deposits called fingerprint profiles, and routine light microscopy of a peripheral blood smear may show lymphocyte vacuoles.

### 599.3 Adrenoleukodystrophy

Jennifer M. Kwon

See Chapter 86.2.

### 599.4 Sialidosis

Jennifer M. Kwon

Sialidosis is the result of lysosomal sialidase deficiency, secondary to autosomal recessive mutations in the sialidase (α-neuraminidase, *NEU1* gene on chromosome 6p21.3). The accumulation of sialic acid–oligosaccharides with markedly increased urinary excretion of sialic acid–containing oligosaccharides is associated with clinical presentations that range from the milder sialidosis type I to the more severe sialidosis type II associated with both neurologic and somatic features.

**Sialidosis type I**, the cherry-red spot myoclonus syndrome, usually presents in the 2nd decade of life, when a patient complains of visual deterioration. Inspection of the retina shows a cherry-red spot, but, unlike patients with TSD, visual acuity declines slowly in individuals with cherry-red spot myoclonus syndrome. Myoclonus of the extremities is gradually progressive and often debilitating and eventually renders patients nonambulatory. The myoclonus is triggered by voluntary movement, touch, and sound and is not controlled with anticonvulsants. Generalized convulsions responsive to antiepileptic drugs occur in most patients.

**Sialidosis type II** patients present at a younger age and have cherry-red spots and myoclonus, as well as somatic involvement, including coarse facial features, corneal clouding (rarely), and dysostosis multiplex, producing anterior beaking of the lumbar vertebrae. Type II patients may be further subclassified into congenital and infantile (childhood) forms, depending on the age at presentation. Examination of lymphocytes shows vacuoles in the cytoplasm, biopsy of the liver demonstrates cytoplasmic vacuoles in Kupffer cells, and membrane-bound vacuoles are found in Schwann cell cytoplasm, all attesting to the multigorgan nature of sialidosis type II. No distinctive neuroimaging findings or abnormalities in electrophysiologic studies are noted in this group of disorders. Patients with sialidosis have been reported to live beyond the 5th decade.

Some cases of what appears to be sialidosis type II are the result of combined deficiencies of β-galactosidase and α-neuraminidase resulting from deficiency of protective protein/cathepsin A that prevents premature intracellular degradation of these 2 enzymes. These patients have galactosialidosis and they are clinically indistinguishable from those with sialidosis type II. Consequently, patients who have features of sialidosis type II with marked urinary excretion of oligosaccharides should be tested for protective protein/cathepsin A deficiency as well as sialidase deficiency.

### 599.5 Miscellaneous Disorders

Jennifer M. Kwon

**PELIZAEUS-MERZBACHER DISEASE** Pelizaeus-Merzbacher disease (PMD) is an X-linked recessive disorder characterized by nystagmus and abnormalities of myelin. PMD is caused by mutations in the proteolipid protein (*PLP1*) gene, on chromosome Xq22, which is essential for CNS myelin formation and oligodendrocyte differentiation. Mutations in the same gene can cause familial spastic paraparesis (progressive spastic paraparesis type 2, *SPG2*). *PLP1* mutations causing disease include point mutations, deletions, gene duplications, and other gene dosage changes.

Clinically, classic PMD is recognized by nystagmus and roving eye movements with head nodding during infancy. Developmental milestones are delayed; ataxia, choreoathetosis, and spasticity ultimately develop. Optic atrophy and dysarthria are associated findings, and death occurs in the 2nd or 3rd decade. The major pathologic finding is a loss of myelin with intact axons, suggesting a defect in the function of oligodendroglia. An MRI scan shows a symmetric pattern of delayed myelination. Multimodal-evoked potential studies demonstrate early in the course a pattern consisting of loss of waves III-V on the auditory brainstem response. This finding is useful in the investigation of nystagmus in infant boys. VEPs show prolonged latencies, and somatosensory evoked potentials show absent cortical responses or delayed latencies. It is now recognized that a broad spectrum of phenotypes, including *SPG2* and peripheral nerve abnormalities, can also result from mutations in the *PLP1* gene.

There is a PMD-like syndrome caused by autosomal recessive mutations in the gap junction protein alpha 12 (*GJA12*, or connexin 47). Individuals with *GJA12* mutations have a clinical and radiologic phenotype like PMD including hypomyelinating leukodystrophy.

**ALEXANDER DISEASE** This is a rare disorder that causes progressive macrocephaly and leukodystrophy. Alexander disease is caused by dominant mutations in the glial fibrillary acidic protein (*GFAP*) gene, on chromosome 17q21.

*Bibliography is available at Expert Consult.*
Bibliography
Bibliography

and cases are usually sporadic in their families. Pathologic examination of the brain discloses deposition of eosinophilic hyaline bodies called Rosenthal fibers in astrocyte processes. These accumulate in a perivascular distribution throughout the brain. In the classic infantile form of Alexander disease, degeneration of white matter is most prominent frontally. Diagnosis may be suggested by MRI (Fig. 599-3) and MR spectroscopy demonstrating abnormal metabolic substrates. Affected children develop progressive loss of intellect, spasticity, and unresponsive seizures causing death by 5 yr of age. However, there are milder forms that present later in life and that may not have the characteristic frontally predominant or megalencephaly.

**CANAVAN SPONGY DEGENERATION**

See Chapter 85.15.

**OTHER LEUKODYSTROPHIES**

Metabolic and degenerative disorders can present with significant cerebral white matter changes, such as some mitochondrial disorders (see Chapters 86.1 and 598.2) and glutaric aciduria type 1 (see Chapter 85.14). In addition, the broader use of MRI has brought to light new leukodystrophies. One example is vanishing white matter disease or childhood ataxia with CNS hypomyelination characterized by ataxia and spasticity. Some patients also have optic atrophy, seizures, and cognitive deterioration. The age of presentation and the rapidity of decline can be quite variable. In the early-onset forms, decline is usually rapid and followed quickly by death; in the later-onset forms, mental decline is usually slower and milder. Interestingly, acute demyelination in these disorders can be triggered by fever or fright. The diagnosis of vanishing white matter disease or childhood ataxia with CNS hypomyelination is based on clinical findings, characteristic abnormalities on cranial MRI, and autosomal recessive mutations in 1 of 5 causative genes (EIF2B1, EIF2B2, EIF2B3, EIF2B4, and EIF2B5) encoding the 5 subunits of the eucaryotic translation initiation factor, eIF2B.

**MENKES DISEASE**

Menkes disease (kinky hair disease) is a progressive neurodegenerative condition inherited as a X-linked recessive trait. The Menkes gene codes for a copper-transporting, P-type adenosine triphosphatase, and mutations in the protein are associated with low serum copper and ceruloplasmin levels, as well as a defect in intestinal copper absorption and transport. Symptoms begin in the 1st few mo of life and include hypothermia, hypotonia, and generalized myoclonic seizures. The facies are distinctive, with chubby, rosy cheeks and kinky, colorless, friable hair. Microscopic examination of the hair shows several abnormalities, including trichorrhexis nodosa (fractures along the hair shaft) and pili torti (twisted hair). Feeding difficulties are prominent and lead to failure to thrive. Severe mental retardation and optic atrophy are constant features of the disease. Neuropathologic changes include tortuous degeneration of the gray matter and marked changes in the cerebellum with loss of the internal granule cell layer and necrosis of the Purkinje cells. Death occurs by 3 yr of age in untreated patients.

Copper-histidine therapy may be effective in preventing neurologic deterioration in some patients with Menkes disease, particularly when treatment is begun in the neonatal period or, preferably, with the fetus. These presymptomatic children are currently identified because of a family history of an affected brother. Copper is essential in the early stages of CNS development, and its absence probably accounts for the neuropathologic changes. Infants diagnosed presymptomatically in the 1st 10 days of life can be started on an experimental protocol of daily copper-histidine subcutaneous injections (as of 2015, only available at NIH under a program supervised by Dr. Stephen Kaler). Optimal response to copper-histidine injection treatment appears to occur only in patients who are identified in the newborn period and whose mutations permit residual copper-transport activity.

The occipital horn syndrome, a skeletal dysplasia caused by different mutations in the same gene as that involved in Menkes disease, is a relatively mild disease. The 2 diseases are often confused, because the biochemical abnormalities are identical. Resolution of the uncertainty about treatment of patients with Menkes disease will require careful genotype-phenotype correlation, along with further clinical trials of copper therapy.

**RET SYNDROME**

This syndrome is not strictly speaking a degenerative disease, but a disorder of early brain development marked by a period of developmental regression and deceleration of brain growth after a relatively
normal neonatal course. It occurs predominantly in girls. The frequency is approximately 1 in 15,000-22,000 children. Rett syndrome is caused by mutations in MeCP2, a transcription factor that binds to methylated CpG islands and silences transcription. Development may proceed normally until 1 yr of age, when regression of language and motor milestones and acquired microcephaly become apparent. An ataxic gait or fine tremor of hand movements is an early neurologic finding. Most children develop peculiar sighing respirations with intermittent periods of apnea that may be associated with cyanosis. The hallmark of Rett syndrome is repetitive hand-wringing movements and a loss of purposeful and spontaneous use of the hands; these features may not appear until 2-3 yr of age. Autistic behavior is a typical finding in all patients. Generalized tonic-clonic convulsions occur in the majority and are usually well controlled by anticonvulsants. Feeding disorders and poor weight gain are common. After the initial period of neurologic regression, the disease process appears to plateau, with persistence of the autistic behavior. Cardiac arrhythmias may result in sudden, unexpected death at a rate that is higher than the general population. Generally girls survive into adulthood.

Postmortem studies show significantly reduced brain weight (60-80% of normal) with a decrease in the number of synapses, associated with a decrease in dendritic length and branching. The phenotype may be related to failure to suppress expression of genes that are normally silent in the early phases of postnatal development. Although very few males survive with the classic Rett syndrome phenotype, genotyping of boys without the classic Rett syndrome phenotype but with intellectual disability and other atypical neurologic features has detected a significant number with mutations in MeCP2. Mutations in MeCP2 have been demonstrated in normal female carriers, females with Angelman syndrome, and in males with fatal encephalopathy, Klinefelter (47 XXY) syndrome, and familial X-linked mental retardation.

Some girls have an atypical Rett phenotype associated with severe myoclonic seizures in infancy, slowing of head growth, and developmental arrest and have mutations in another X-linked gene encoding for cyclin-dependent kinase–like 5 (CDKL5), which may interact with MeCP2 and other proteins regulating gene expression.

### SUBACUTE SCLEROSING PANENCEPHALITIS

This is a rare, progressive neurologic disorder caused by persistent measles virus infection of the CNS (see Chapter 246). The number of reported cases has decreased dramatically to 0.06 cases/million population, paralleling the decline in reported measles cases. The initial clinical manifestations include personality changes, aggressive behavior, and impaired cognitive function in individuals who have been exposed to natural measles virus in early childhood. Myoclonic seizures soon dominate the clinical picture. Later, generalized tonic-clonic convulsions, hypertonia, and choreoathetosis become evident, followed by progressive bulbar palsy, hyperthermia, and decerebrate postures. Funduscopic examination early in the course of the disease reveals papilledema in approximately 20% of the cases. Optic atrophy, chorioretinitis, and macular pigmentation are observed in most patients. The diagnosis is established by the typical clinical course and 1 of the following: (1) measles antibody detected in the cerebrospinal fluid, (2) a characteristic electroencephalogram consisting of bursts of high-voltage slow waves interspersed with a normal background that occur with a constant periodicity in the early stages of the disease, and (3) typical histologic findings in the brain biopsy or postmortem specimen. Treatment with a series of antiviral agents has been attempted without success. Death occurs usually within 1-2 yr from the onset of symptoms.

### NEURODEGENERATION WITH BRAIN IRON ACCUMULATION

Neurodegeneration with brain iron accumulation represents multiple, age-of-onset-dependent disorders characterized by extrapyramidal symptoms, intellectual deterioration and regression, with iron deposition in the basal ganglia. There is significant phenotype variability of these disorders; however, a characteristic finding on MRI demonstrates symmetric T2 signal homogeneous hypointensity. Common neurodegeneration with brain iron accumulation disorders are distinguished in Table 599-3 and an approach to their diagnosis is noted in Figure 599-4. Clinical features, which are highly variable, may include dystonia, parkinsonism, ataxia, spasticity, psychiatric symptoms, and intellectual impairment. Treatment should focus on the specific disorder and is usually symptomatic relief rather than curative. Iron chelation has been attempted without major long-term benefit.

From Schneider SA, Zora G, Nardocci N. Pathophysiology and treatment of neurodegeneration with brain iron accumulation in the pediatric population, Curr Treat Option Neurol 15:652-667, 2013, Table 1.
Acquired demyelinating disorders of the central nervous system (CNS) result in neurologic dysfunction caused by immune-mediated attacks on white matter insulating the brain, optic nerves and spinal cord. The white matter is insulated by myelin contained within oligodendrocytes wrapping around nerve axons. In contrast to genetically determined leukodystrophies (sometimes called dysmyelinating disorders) that produce disrupted white matter, acquired demyelinating disorders generally target normally formed white matter. Pediatric demyelinating syndromes are characterized clinically by (1) localization of neurologic deficits (i.e., single site, such as spinal cord [transverse myelitis], optic nerves [optic neuritis] or brainstem, vs polyregional demyelination); (2) the presence vs absence of encephalopathy; and (3) disease course (i.e., monophasic vs repeated attacks involving either the same or new CNS regions). Major demyelinating disorders in childhood include acute disseminated ecephalomyelitis (ADEM), typically a self-limited disorder, and relapsing–remitting multiple sclerosis (MS). MRI of brain and spine is useful to initially characterize asymptomatic and clinically silent demyelinating lesions, but serial MRI is often required to distinguish self-limited vs chronic demyelinating syndromes, especially in the younger child. Additional studies, such as cerebrospinal fluid (CSF) analysis, autoimmune and genetic testing, and sometimes even brain biopsy, may be required to evaluate for mimickers of demyelination, such as neoplasm, infection, systemic rheumatologic disorders, isolated CNS angiitis, mitochondrial disease, and leukodystrophies (Tables 600-1 and 600-2).

600.1 Multiple Sclerosis
Jayne M. Ness

Pediatric MS is a chronic demyelinating disorder of the brain, spinal cord, and optic nerves characterized by a relapsing–remitting course of neurologic events without encephalopathy separated in time and space.

Epidemiology
Pediatric MS is rare, with an estimated 2-5% of MS patients experiencing their first symptoms before age 18 yr. Pediatric MS has a slight male predominance when disease onset is before age 6 yr, but by age 12 yr, females outnumber males 2:1.

Pathogenesis
A complex interplay of environmental, infectious, and genetic factors influence MS susceptibility. Immune system dysregulation involving T and B lymphocytes triggers inflammation, axonal demyelination, axonal loss, and regeneration within both white and gray matter. Inflammatory infiltrates within actively demyelinating lesions of relapsing-remitting MS are targets for disease modifying agents (DMAs). Neurodegenerative changes predominate in progressive forms of MS.

</table>

The 2001 McDonald MRI criteria for DIS require 3 of the following 4 MRI features: 29 T2 lesions or 1 gadolinium-enhancing lesion; 23 periventricular lesions; 21 infratentorial lesion(s); 21 juxtacortical lesion(s). The DIT criteria require subsequent white-matter lesions whose timing depends on the temporal relation of the initial MRI with the onset of the clinical symptoms.

The 2010 Revised McDonald MRI criteria for DIS require the presence of at least 2 of the following 4 criteria: 21 lesions in each of the 4 locations; periventricular, juxtacortical, infratentorial, and spinal cord. The 2010 Revised McDonald MRI criteria for DIT can be satisfied either by the emergence of new T2 lesions (with or without enhancement) on serial scan(s) or can be met on a single baseline scan if there exists simultaneous presence of a clinically silent gadolinium-enhancing lesion and a nonenhancing lesion.

Chapter 600

◆

Demyelinating Disorders of the Central Nervous System

2921

TREATMENT

Relapses causing functional disability may be treated with methylprednisolone, 20–30 mg/kg/day (max: 1,000 mg/day) for 3–5 days, with or without prednisone taper. DMAs reduce relapse frequency and T2 lesion load, mainly by targeting the inflammatory response that predominates during the relapsing-remitting phase of MS (Table 600-6). There are 4 injectable DMAs, 3 oral DMAs, and 2 infused DMAs approved by the FDA for adult MS, but to date, none of these agents has a pediatric MS indication. Injectable agents, first approved in the mid-1990s (interferon-beta1α SC or IM or interferon-beta1β SC; glatiramer acetate SC) have some side effects such as flu-like side effects and risk of transaminase elevation with interferon-beta or requirement for daily injections with glatiramer but otherwise have an excellent safety record so are still recommended as first-line therapy in pediatric MS. Three oral DMAs (fingolimod, teriflunomide, dimethyl fumarate) have been FDA-approved since 2010, but despite ease of oral administration, enthusiasm is tempered by reports of severe side effects or even death from reactivation of latent viruses (fingolimod, dimethyl fumarate) and potential of severe birth defects (teriflunomide). Intravenous DMAs (natalizumab, mitoxantrone) are second-line agents.

COMPLICATIONS

Similar to adults with MS, pediatric MS patients can acquire fixed neurologic deficits affecting vision and other cranial nerves, motor and sensory function, balance, and bowel/bladder function. Cognitive impairment can impede academic achievement.

Figure 600-1 Criteria for the diagnosis of multiple sclerosis. The principle is to establish dissemination in time and place of lesions, meaning that episodes affecting separate sites within the central nervous system have occurred at least 30 days apart. MRI can substitute for 1 of these clinical episodes. Dissemination in time of magnetic resonance lesions requires simultaneous presence of asymptomatic gadolinium-enhancing and asymptomatic lesions or followup MRI showing accumulation of a new gadolinium-enhancing lesion or T2 lesion. Criteria for MRI definition of dissemination in space require 2 or more lesions in periventricular, juxtacortical, or infratentorial regions or spine. Primary progressive MS is very rare in childhood but can be diagnosed after 1 yr of a progressive deficit and 2 of the following: (1) a positive brain MRI; (2) a positive spinal cord MRI; and (3) positive oligoclonal bands. Patients having an appropriate clinical presentation but who do not meet all of the diagnostic criteria can be classified as having possible MS. CSF, cerebrospinal fluid. (From Compston A, Coles A: Multiple sclerosis, Lancet 372:1502–1517, 2008, Fig. 1.)

syndromes such as ADEM or NMO, especially in the prepubertal child. ADEM is a self-limited syndrome characterized by encephalopathy, polyregional neurologic deficits, and diffuse multifocal MRI T2 abnormalities followed by subsequent clinical improvement and resolution of MRI T2 lesions (see Tables 600-1, 600-2, 600-4, and 600-5). However, a subset of pediatric MS patients (10–25%) presents with an ADEM phenotype and then experiences multiple relapses with accumulation of MRI T2 lesions. NMO, traditionally thought of as a combined myelitis and optic neuritis with normal brain MRI, now has a broader phenotype with the identification of the NMO antibody against the CNS water channel aquaporin-4 and MRI lesions in the brain. The NMO spectrum includes isolated bilateral optic neuritis or longitudinally extensive transverse myelitis even in the presence of brain MRI abnormalities or encephalopathy.

used only after failure of first-line injectable or oral agents. Natalizumab therapy is associated with the risk of developing progressive multifocal encephalopathy (CNS infection with human polyomavirus JC). Mitoxantrone has a lifetime dose limit because of cardiotoxicity and is associated with subsequent development of acute myelogenous lymphoma in 2 of 802 MS patients (0.25%).

**PROGNOSIS**

Retrospective studies of patients diagnosed with MS prior to widespread dimethyltryptamine use suggest slower disease progression in pediatric MS patients compared to adults. Despite a longer time to irreversible disability (20-30 yr), pediatric MS patients acquire irreversible disability at a younger age than adults.

**600.2 Neuromyelitis Optica**

Jayne M. Ness

NMO (Devic disease) is a demyelinating disorder characterized by monophasic or polyphasic episodes of optic neuritis and/or transverse myelitis. It was once thought that NMO was a variant of MS, but identification of the NMO antibody against the aquaporin-4 water channel has broadened the spectrum of NMO to include brainstem syndromes and recurrent forms of optic neuritis and transverse myelitis (see Table 600-2). NMO spectrum disorder frequently involves symptomatic or silent MRI lesions demonstrating demyelination of the cerebral cortex and other regions of the brain.

**Epidemiology**

NMO has an age of onset of 31.2 ± 11 yr. In 1 study, in monophasic patients, the range of age of onset was 1-54 yr; in polyphasic patients, the range was 6-72 yr. NMO is more common in females than in males; 65% of monophasic and 80-85% of polyphasic NMO patients are female. It is also more common in Asians than in blacks or whites and appears to have a higher mortality rate in individuals of African descent than in others.

**Pathogenesis**

NMO is associated with IgG antibodies against the aquaporin-4 water channel, which is most abundant on astrocyte foot processes within periventricular regions, brainstem, optic nerves, and spinal cord. Antibody binding to aquaporin-4 activates the classical complement pathway with C5b-9 components leading to leukocytes attraction and degranulation, causing astrocyte death. Chemokines from dying astrocytes and activated leukocytes attract macrophages, leading to death of oligodendrocytes and neurons with subsequent necrosis or even cavitation in affected tissues. Although most cases of NMO are idiopathic and only occasional familial cases have been reported, there have been reports of postinfectious NMO. HIV, syphilis, chlamydia, varicella, cytomegalovirus, and Epstein-Barr virus are associated with subsequent development of NMO. Aquaporin-4 antibody–positive NMO may follow or occur simultaneously with N-methyl-D-aspartate receptor antibody autoimmune encephalitis.

**Clinical Manifestations**

NMO presents with optic neuritis or transverse myelitis or brainstem symptoms such as intractable vomiting or hiccups, diplopia, facial...

ADEM, acute disseminated encephalomyelitis; MS, multiple sclerosis.

weakness or numbness or dysphagia. Optic neuritis or transverse myelitis may occur simultaneously or may be separated in time by weeks or even years. Some present with an encephalopathy mimicking ADEM. Others exhibit endocrinopathies such as the syndrome of inappropriate antidiuretic hormone secretion, diabetes insipidus, or disrupted puberty. The symptoms and signs of transverse myelitis depend on the spinal level and completeness of the inflammatory changes. NMO differs from MS in that recovery of visual and spinal cord function is generally not as complete after each episode; optic neuritis is more frequently bilateral in NMO than in MS.
LABORATORY FINDINGS
CSF in patients with NMO often has 50 or more white blood cells per microliter. Unlike MS, it is devoid of oligoclonal bands. Serum positivity for anti–aquaporin-4 antibodies (so-called NMO antibodies) has a sensitivity of 73% and a specificity of 91% for NMO. Neuroimaging studies should include the entire spine, optic nerves as well as the cortex that may reveal lesions in the brainstem or thalamus or hazy ill-defined lesions in the hemispheres in contrast to the discrete, well-defined oval lesions in the periventricular white matter seen in MS.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS
Clinical diagnosis of NMO currently requires optic neuritis and transverse myelitis plus at least 2 of 3 supporting criteria: (1) brain MRI not diagnostic of MS, (2) seropositivity for anti–aquaporin-4 antibody, or (3) spine MRI with longitudinally extensive transverse myelitis involving at least 3 spinal segments (see Table 600-2). NMO spectrum disorder may be diagnosed in relapsing forms of transverse myelitis or optic neuritis with aquaporin-4 seropositivity. The differential diagnosis includes MS; ADEM (see Chapter 600.3); rheumatologic etiologies producing transverse myelitis, and/or optic neuritis, including systemic lupus erythematosus, Behçet disease, and neurosarcoïdosis (usually accompanied by other nonneurologic manifestations); idiopathic transverse myelitis, tropical spastic paraparesis, and viral encephalomyelitis (none of which have NMO antibodies in the serum or CSF); and metabolic and idiopathic causes of isolated optic neuritis or other acute monocular or binocular visual loss. Additional considerations depending on the location of the lesions include lymphoma, Langerhans cell histiocytosis, tuberculosis, and vitamin B12 or E deficiencies.

COMPLICATIONS
Similar to adults with NMO, pediatric NMO patients often are left with fixed neurologic deficits affecting visual acuity, visual fields, color vision, motor and sensory function, balance, and bowel/bladder function.

TREATMENT
Initial episodes and relapses may be treated acutely with methylprednisolone, 20-30 mg/kg/day (max: 1,000 mg/day) for 3-5 days, followed by a slow prednisone taper. Rituximab is effective in preventing relapses of NMO and NMO spectrum disorder. Preliminary evidence suggests that eculizumab also reduced recurrences and may improve disability in patients with severe NMO spectrum disorder.

PROGNOSIS
The prognosis is generally poor for patients with NMO. In 1 study, approximately 20% remained functionally blind (i.e., 20/200 vision or worse) in at least 1 eye and 31% had permanent monoplegia or paraplegia. Five-year survival of the patients with paraplegia is approximately 90%.

Bibliography is available at Expert Consult.

600.3 Acute Disseminated Encephalomyelitis
Jayne M. Ness

ADEM is an initial inflammatory, demyelinating event with multifocal neurologic deficits, typically accompanied by encephalopathy (see Table 600-2).

EPIDEMIOLOGY
ADEM can occur at any age but most series report a mean age between 5 and 8 yr with a slight male predominance. Reported incidence ranges from 0.07-0.4 per 100,000 per year in the pediatric population.

PATHOGENESIS
Molecular mimicry induced by infectious exposure or vaccine may trigger production of CNS autoantigens. Many patients experience a transient febrile illness in the month prior to ADEM onset. Preceding infections associated with ADEM include influenza, Epstein-Barr virus, cytomegalovirus, varicella, enterovirus, measles, mumps, rubella, herpes simplex, and Mycoplasma pneumoniae. Postvaccination ADEM has been reported following immunizations for rabies, smallpox, measles, mumps, rubella, Japanese encephalitis B, pertussis, diphtheria-polio-tetanus, and influenza.

CLINICAL MANIFESTATIONS
Initial symptoms of ADEM may include lethargy, fever, headache, vomiting, meningeal signs, and seizures, including status epilepticus. Encephalopathy is a hallmark of ADEM, ranging from ongoing confusion to persistent irritability to coma. Focal neurologic deficits can be difficult to ascertain in the obtunded or very young child but common neurologic signs in ADEM include visual loss, cranial neuropathies, ataxia, motor and sensory deficits, plus bladder/bowel dysfunction with concurrent spinal cord demyelination.

NEUROIMAGING
Head CT may be normal or show hypodense regions. Cranial MRI, the imaging study of choice, typically exhibits large, multifocal and sometimes confluent or large edematous mass-like tumefactive T2 lesions with variable enhancement within white and often gray matter of the cerebral hemispheres, cerebellum, and brainstem (Fig. 600-2). Deep gray-matter structures (thalamus, basal ganglia) are often involved, although this may not be specific to ADEM. Spinal cord may have abnormal T2 signal or enhancement, with or without clinical signs of myelitis. MRI lesions of ADEM typically appear to be of similar age but their evolution may lag behind the clinical presentation. Serial MRI imaging 3-12 mo following ADEM shows improvement and often complete resolution of T2 abnormalities, although residual gliosis may remain.

Figure 600-2
Axial T2-weighted fluid-attenuated inversion recovery MRI of the brain in a child with acute disseminated encephalomyelitis. High signal (white) lesions in the T2-weighted image reflect areas of demyelination and edema in deep subcortical and periventricular white matter as well as the basal ganglia and thalamus on the left side.
Bibliography

Figure 600-3 MRI findings in acute disseminated encephalomyelitis. Multiple scattered T2 hyperintensities are appreciated on fluid-attenuated inversion recovery images (A) with evidence of hemorrhage on susceptibility-weighted images (B), contrast enhancement on T1 postgadolinium images (C), and without diffusion restriction on diffusion-weighted imaging (D). (From Virmani T, Agarwal A, Klawiter EC: Clinical reasoning: a young adult presents with focal weakness and hemorrhagic brain lesions. Neurology 76:e105–e109, 2011, Fig. 2.)

Severe involvement may progress to an acute hemorrhagic leukoencephalopathy (Hurst disease) with large lesions, edema, mass effect, and a polymorphonucleated cell pleocytosis (in contrast to lymphocytic pleocytosis in the CSF noted in typical ADEM) (Fig. 600-3).

LABORATORY FINDINGS
There is no biologic marker for ADEM and laboratory findings can vary widely. CSF studies often exhibit pleocytosis with lymphocytic or monocytic predominance. CSF protein can be elevated, especially on repeat studies. Up to 10% of patients with ADEM have oligoclonal bands in the CSF and/or elevated CSF immune globulin production. Patients with ADEM may occasionally demonstrate antibodies against myelin oligodendrocyte glycoprotein, or anti-N-methyl-d-aspartate receptor antibodies. Electroencephalograms often show generalized slowing, consistent with encephalopathy, although polyregional demyelination of ADEM can also cause focal slowing or epileptiform discharges.

DIFFERENTIAL DIAGNOSIS
The differential diagnosis for ADEM is broad but can be narrowed by careful history, appropriate laboratory evaluations, and MRI (see Table 600-1). Empirical antibiotic and antiviral treatment should be considered while infectious evaluations are pending. Follow-up MRI examinations 3-12 mo after ADEM should show improvement; new or enlarging T2 lesions should prompt reevaluation for other etiologies such as MS, leukodystrophies, tumor, vasculitis, or mitochondrial, metabolic, or rheumatologic disorders (see Table 600-1 and Table 600-5).

TREATMENT
Although there are no randomized controlled trials to compare acute treatments for ADEM or other demyelinating disorders of childhood, high-dose intravenous steroids are commonly employed (typically methylprednisolone 20-30 mg/kg per day for 5 days with a maximum dose of 1,000 mg per day). An oral prednisone taper over 1 mo may prevent relapse. Other treatment options include intravenous immune globulin (usually 2 g/kg administered over 2-5 days) or plasmapheresis (typically 5-7 exchanges administered every other day). In severe cases of suspected ADEM, rituximab or cyclophosphamide have been used. There is no consensus about timing of these treatments for ADEM.

PROGNOSIS
Many children experience full recovery after ADEM but some are left with residual motor and/or cognitive deficits. ADEM is usually a monophasic illness but demyelinating symptoms can fluctuate for several months. Repeated bouts of demyelination more than 3 mo after ADEM later raise the question of MS vs repeated ADEM.

Bibliography is available at Expert Consult.
Bibliography
Stroke is an important cause of acquired brain injury in newborns and children. The ischemic varieties of arterial ischemic stroke (AIS) and cerebral sinovenous thrombosis (CSVT) are more common than brain malignancy (incidence approximately 5 in 100,000 children per year). Perinatal stroke is even more common and is the leading cause of hemiparetic cerebral palsy. A similar number of children suffer from hemorrhagic stroke (HS) and other forms of cerebrovascular disease. Acute stroke is a neurologic emergency; however, delays in recognition are common and delayed treatment worsens outcomes. In contrast to stroke in adults, there are a diverse group of disorders producing stroke in neonates and children.

601.1 Arterial Ischemic Stroke

Arterial blood reaches the brain via the anterior (internal carotid) and posterior (vertebrobasilar) circulations, converging at the circle of Willis. Strokes most often involve the middle cerebral artery territory but can occur in any cerebral artery of any size. AIS is the focal brain infarction that results from occlusion of these arteries and is a leading cause of acquired brain injury in children with the perinatal period carrying the highest risk.

The diagnosis of stroke in children is frequently delayed. This is a consequence of subtle and nonspecific clinical presentations, poor awareness by primary care pediatric physicians, a complicated differential diagnosis (see Chapter 601.4), and a high frequency (>50%) of negative initial CT scan. The acute onset of a focal neurologic deficit in a child is stroke until proven otherwise. The most common focal presentation is hemiparesis, but acute visual, speech, sensory, or balance deficits also occur. Children with these presentations require urgent neuroimaging and consultation with a child neurologist, as emergency interventions may be indicated. AIS is a clinical and radiographic diagnosis. Although CT imaging can demonstrate mature AIS and exclude hemorrhage, MRI is required to identify early and small infarcts. Diffusion-weighted MRI demonstrates AIS within minutes of onset and up to 7 days postonset; MR angiography can confirm vascular occlusion and suggest possible arteriopathy (Fig. 601-1). Diffusion-weighted MRI can also demonstrate wallerian degeneration.
in the descending corticospinal tract, which correlates with chronic hemiparesis.

Many possible risk factors for AIS are recognized (Table 601-1), although the specific pathophysiologic mechanisms are often poorly understood. Three main categories of etiology should be considered: arteriopathy, cardiac, and hematologic; full investigation, however, often reveals multiple risk factors per individual.

Arteriopathy refers to disorders of the cerebral arteries and is a leading cause of childhood AIS, present in more than 50% of children. A common syndrome affecting healthy school-age children features unilateral irregular stenosis of the proximal middle cerebral artery and neighboring arteries presenting with basal ganglia infarction. The description of this entity has been published under multiple names—transient cerebral arteriopathy, postvaricella angiopathy, nonprogressive childhood primary angiitis of the central nervous system, and focal cerebral arteriopathy—reflecting uncertainty regarding the pathogenesis.

This entity may represent focal inflammation or intracranial dissection or early moyamoya disease, although it is nearly always self-limited. Diffuse, bilateral, progressive vasculitis is rare and can represent progressive childhood primary angiitis of the central nervous system or be associated with systemic vasculitides (Table 601-2). Cranial infections (e.g., bacterial meningitis) also produce arteritis and thrombophlebitis of surface vessels. Arterial dissection can be spontaneous or post-traumatic and can affect extra- or intracranial arteries. Moyamoya syndrome may be idiopathic or associated with other conditions (neurofibromatosis type 1, trisomy 21, Alagille syndrome, sickle cell anemia, chromosomal microdeletions/microduplications, postirradiation) and demonstrates progressive occlusion of the distal internal carotid arteries. Congenital malformations of the cranio-cervical arteries, including PHACES (posterior fossa abnormalities, hemangioma, and arterial, cardiac, eye, and sternal abnormalities) syndrome, or fibromuscular dysplasia may predispose to AIS. Vasospasm as occurs in migraine, subarachnoid hemorrhage or reversible cerebral vasoconstriction syndrome (sometimes called Call-Fleming syndrome) can cause AIS.

Cardioembolic stroke makes up approximately 25% of childhood AIS with maximal embolic risk concurrent with catheterization, surgical repair, or ventricular assistive device use. AIS complicates approximately 0.5% of pediatric cardiac surgeries and reoperation increases the risk. Although complex congenital heart diseases are most frequently associated with AIS, acquired conditions, including arrhythmia, cardiomyopathy, and infective endocarditis, also should be considered. A patent foramen ovale provides the possibility of paradoxical venous thromboembolism but is not likely an independent risk factor. All children with suspected AIS require thorough cardiovascular examination, electrocardiogram, and echocardiogram.

Modified from Roach ES, Golomb MR, Adams R, et al: Management of stroke in infants and children. Stroke 39:2644–2691, 2008, Table 2, p. 6.
Prothrombotic coagulation disorders and infection at index stroke increase stroke recurrence risk.

Hematologic disorders associated with AIS include sickle cell anemia, in which stroke risk is increased 400-fold, although effective screening (transcranial Doppler) and treatments (transfusions) have reduced the incidence. Iron-deficiency anemia also increases the risk and is easily treatable. Coagulation disorders are associated with childhood AIS. They include hereditary (e.g., factor V Leiden) and acquired (e.g., antiphospholipid antibodies, lipoprotein-a elevation) prothrombotic states and prothrombotic medications, including oral contraceptives and aspiraginase chemotherapy. Additional AIS risk factors include migraine, acute childhood illnesses, chronic systemic illnesses, illicit drugs and toxins, and rare inborn errors of metabolism.

Treatment of childhood AIS is multifaceted and multiple consensus-based guidelines are available. Given the inadequate safety data, emergency thrombolysis is not recommended for children, but safety studies are underway. Early initiation of antithrombotic strategies is paramount to prevent early reinfarction. Depending on the suspected cause, this includes anticoagulation with hepatins or antiplatelet strategies, usually aspirin. Hyperacute neuroprotective strategies are essential to initiate with suspected stroke as they prevent progressive ischemic brain injury. These include control of blood glucose, temperature and seizures and maintenance of cerebral perfusion pressure.

Early malignant cerebral edema is life-threatening, more common in children and predictable, and emergency surgical decompression can be life-saving. Disease-specific treatments include transfusion therapy in sickle cell disease, immunosuppression in vasculitis, and revascularization surgery in moyamoya. Long-term treatment goals include secondary stroke prevention, including antithrombotic therapy in arteriopathy and anticoagulation in cardiogenic causes. Multimodal, family-centered rehabilitation programs are required for most survivors, targeting motor deficits, language and intellectual impairments, behavioral and social disabilities, and epilepsy. Long-term attention to arterial health lifestyle factors may also be important. Outcomes after childhood stroke include recurrent stroke ranging from 10-50% depending on cause and preventative treatment, death in 6-10%, neurologic deficits in 60-70%, and seizure disorders in up to 30%.

**PERINATAL ARTERIAL ISCHEMIC STROKE**

Perinatal stroke is very common, differs from childhood stroke, and has 2 distinct clinical presentations. Acute symptomatic neonatal AIS presents with focal seizures at 24-28 hr of life (Fig. 601-2). MRI diffusion

**Figure 601-2 Perinatal arterial ischemic stroke.** A term newborn developed focal right-sided seizures at 16 hr of life. **A**, Diffusion-weighted MRI on day 2 diagnoses neonatal arterial ischemic stroke by demonstrating restricted diffusion in the left middle cerebral artery territory. **B**, Repeat MRI at 12 mo shows cystic encephalomalacia and scarring in the same territory, a similar appearance to children diagnosed with presumed perinatal arterial ischemic stroke later in infancy.
abnormalities in an arterial territory confirm recent infarction. Alternatively, infants are asymptomatic at birth and present in later infancy with signs of early hand preference and congenital hemiparesis. Hand dominance within the 1st yr of life is abnormal and may be the result of perinatal stroke. Imaging reveals focal encephalomalacia in an arterial territory, typically large middle cerebral artery lesions.

In acute neonatal AIS, seizure control is important, but antithrombotic agents are rarely required (exception: cardiac embolism). Pathophysiolo$\text{gy is complex and poorly understood. Most are idiopathic, although established causes include congenital heart disease, thrombotic placental pathology, and other prothrombotic disorders and meningi}^\text{tis. Many other maternal, prenatal, perinatal, obstetrical, and neonatal factors have been investigated with several strong associations found (e.g., infertility, primiparity, multiple gestation). Outcomes are poor, with most children having lifelong disability. Perinatal stroke accounts for most cases of hemiparetic cerebral palsy (congenital hemiplegia, see Chapter 598.1). Additional morbidity, seen in approximately 25%, includes disorders of language, learning, cognition, and behavior and longer-term epilepsy. Stroke recurrence rates for both the child and subsequent pregnancies are extremely low.

### 601.2 Cerebral Sinovenous Thrombosis

\textit{Adam Kirton and Gabrielle A. deVeber}

Cerebral venous drainage occurs via the cerebral sinovenous system. This includes superficial (cortical veins, superior sagittal sinus) and deep (internal cerebral veins, straight sinus) systems that converge at the torcula to exit via the paired transverse and sigmoid sinuses and jugular veins. In CSVT, thrombotic occlusion of these venous structures can create increased intracranial pressure, cerebral edema, and, in 50% of cases, venous infarction or hemorrhage (stroke). CSVT may be more common in children than in adults, and risk is greatest risk in the neonatal period.

Clinical presentations are typically gradual, variable, and nonspecific compared to AIS. Neonates often present with encephalopathy and seizures. Children may present with symptoms mimicking idiopathic intracranial hypertension, including progressive headache, papilledema, diplopia secondary to 6th nerve palsy, or with acute focal deficits. Seizures, lethargy, and confusion are common. Diagnosis requires a high clinical suspicion and purposeful imaging of the cerebral venous system. Nonenhanced CT is very insensitive for CSVT, and contrast \textit{CT venography} or MR venography is necessary to demonstrate filling defects in the cerebral venous system (Fig. 601-3). MRI offers superior parenchymal imaging compared to CT.

Table 601-3 lists the risk factors for CSVT. Prothrombotic states associated with childhood CSVT include inherited (e.g., prothrombin gene 20210A mutation) and acquired (e.g., antiphospholipid antibodies) conditions, prothrombotic medications (asparaginase, oral contraceptives) and common childhood illnesses including otitis media, iron-deficiency anemia, and \textit{dehydration}. Systemic diseases associated with increased CSVT risk include leukemia, inflammatory bowel disease, and nephrotic syndrome.

Head and neck disorders can directly involve cerebral veins and sinuses causing CSVT. Common \textit{infections}, including meningitis, otitis media, and mastoiditis, can cause \textit{septic thrombophlebitis} of venous channels. CSVT can complicate head \textit{trauma} especially adjacent to skull fractures. Neurosurgical procedures in proximity to cerebral venous structures may lead to injury and CSVT. Finally, obstruction of the jugular veins and proximal stasis may result in CSVT. In neonates, the unfused status of cranial sutures enables mechanical distortion of underlying venous sinuses during delivery, or postnatally occipital bone compression of the posterior sagittal sinus during supine lying predisposing to CSVT.

\textit{Anticoagulation therapy} plays an important role in childhood CSVT treatment. Substantial indirect evidence has led to consensus to recommend anticoagulation with unfractionated or low-molecular-weight heparins in most children. Hemorrhagic transformation of venous infarcts is not an absolute contraindication. Treatment is usually planned for 6 mo, although if reimaging at 3 mo confirms recanalization, treatment is usually discontinued. However anticoagulation of neonates is more controversial and guidelines differ. Evidence suggests that 30% of untreated neonates and children will extend their thrombosis in the 1st wk postdiagnosis and additional venous infarction can result. Therefore, if anticoagulation is withheld, early (e.g., 5-7

\textbf{Figure 601-3} Cerebral sinovenous thrombosis. A 9 yr old girl presented with fever and progressive right-sided headache. She complained of double vision and had papilledema on examination. Axial (A) and coronal (B) CT venography demonstrates a large thrombus in the right transverse sinus that fails to opacify with contrast (full arrows). Note normal filling in superior sagittal and in smaller left transverse sinuses (empty arrows, right) and opacification of the mastoid air cells (hatched arrow, left). Cause was otitis media/mastoiditis with septic thrombophlebitis of transverse sinus.
Bibliography

601.3 Hemorrhagic Stroke

Adam Kirton and Gabrielle A. deVeber

HS includes nontraumatic intracranial hemorrhage and is classified by the intracranial compartment containing the hemorrhage. Intraparenchymal bleeds may occur in any location, whereas intraventricular hemorrhage may be isolated or an extension of intraparenchymal hemorrhage. Bleeding outside the brain may occur in the subarachnoid, subdural, or epidural spaces.

Clinical presentations vary according to location, cause, and rate of bleeding. Acute hemorrhages may feature instantaneous or thunderclap headache, loss of consciousness, and nuchal rigidity in addition to focal neurologic deficits and seizures. HS can be rapidly fatal. In bleeds associated with vascular malformations, pulsatile tinnitus, cranial bruit, macrocephaly, and high-output heart failure may be present. Diagnosis relies on imaging and CT is highly sensitive to acute HS. However, lumbar puncture may be required to exclude subarachnoid hemorrhage. MRI is highly sensitive to even small amounts of both acute and chronic hemorrhage and offers improved diagnostic accuracy (Fig. 601-4). Angiography by CT, MR, or conventional catheter means is often required to exclude underlying vascular abnormalities (e.g., vascular malformations, aneurysms).

Abusive head trauma with intracranial bleeding in children may present as primary subdural or parenchymal hemorrhage with no apparent history of trauma. Subtle scalp, suborbital, or ear bruising; retinal hemorrhages in multiple layers; and chronic failure to thrive should always be sought, and in infants with subdural bleeds, x-rays performed to rule out fractures. Epidural hematoma is nearly always caused by trauma, including middle meningeal artery injury typically associated with skull fracture. Subdural hematoma can occur spontaneously in children with brain atrophy because of stretching of bridging veins.

Causes of and risk factors for HS (Table 601-4) include vascular malformations and systemic disorders. Arteriovenous malformations
Bibliography
are the most common cause of childhood subarachnoid and intraparenchymal HS and may occur anywhere. Neonates with vein of Galen malformations may present with heart failure, progressive macrocephaly, or, rarely, hemorrhage. In older children with arteriovenous malformations, the risk of bleeding is approximately 2-4% per year throughout life. Other vascular malformations leading to HS include cavernous angiomas ("cavernomas"), dural arteriovenous fistulas, and vein of Galen malformations. Cerebral aneurysms are an uncommon cause of subarachnoid hemorrhage in children and may suggest an underlying disorder (e.g., polycystic kidney disease, infective endocarditis). A common cause for HS is bleeding from a preexisting brain tumor. Arterial diseases that usually cause ischemic stroke, including fibromuscular dysplasia, vasculitis, and moyamoya, can also predispose to HS. Additional causes of parenchymal HS include hypertensive hemorrhage and hematologic disorders such as thrombocytopenic purpura, hemophilia, acquired coagulopathies (e.g., disseminated intravascular coagulopathy, liver failure), anticoagulant therapy (e.g., warfarin), or illicit drug use. Ischemic infarcts may undergo hemorrhagic transformation, particularly in CSVT, and may be difficult to differentiate from primary HS.

Management of acute childhood HS may require emergent neurosurgical intervention for large or rapidly expanding hemorrhage. The same principles of neuroprotection for vulnerable brain suggested in the ischemic stroke sections also apply to HS. Reversal of anticoagulant therapy (with, for example, vitamin K, fresh-frozen plasma) may be required, but the role of other medical interventions, such as factor VII, are unstudied in children. Recurrence risk for those with structural lesions is significant and serial imaging may be required. Definitive repair or removal of the vascular malformation may require a combined approach with interventional endovascular methods or neurosurgery. Outcomes from childhood HS are not well studied but likely depend on lesion size, location, and etiology. Compared with ischemic stroke, HS mortality is higher while long-term deficits are less common.

Neonatal HSs have unique features. Cranial ultrasound can detect many neonatal parenchymal bleeds, especially in the preterm infant where bleeds are located centrally within the cranium and include germinal matrix bleeding and intraventricular hemorrhage (see Chapter 99.3). Germinal matrix injury or bleeding may also occur in utero, resulting in periventricular venous infarction that becomes symptomatic in later infancy as congenital hemiparesis. Subarachnoid and subdural blood may be imaged in up to 25% of normal term newborns. Term HS is poorly studied and includes the etiologies listed above, although HS may be idiopathic in more than 50% of cases. Term intraventricular bleeding is often secondary to deep CSVT with specific management implications.

The Nervous System

2932  Part XXVII  ◆  The Nervous System

601.4  Differential Diagnosis of Stroke-Like Events
Adam Kirton and Gabrielle A. deVeber

The diagnosis of stroke in childhood requires a high index of suspicion balanced with awareness of the differential diagnosis for stroke-like events (Table 601-5). Acute onset of a focal neurologic deficit should be considered stroke until proven otherwise and assessed with neuroimaging. However, pediatric stroke must be differentiated from other stroke-like disorders that may require their own urgent specific treatment.

MIGRAINE
Careful history and examination can often suggest migraine as the cause of acute focal deficits. Migraine auras should last between 5 and 60 min and resolve completely. Neurologic deficits associated with migraine typically evolve slowly compared with stroke, with sensory disturbance or weakness “marching” across body areas over minutes. Although evolution into a migrainous headache is expected, headache may also accompany acute infarction. Furthermore, a group of uncommon migraine subtypes can occur without headache and can more closely mimic stroke in children. These include familial hemiplegic migraine, basilar migraine, and migraine aura without headache. Migraine can also (rarely) cause a stroke, referred to as migrainous infarction.

SEIZURE
Prolonged focal seizure activity is frequently followed by a period of focal neurologic deficit (“Todd’s paresis”) which typically resolves within an hour. Very rarely, focal seizures can manifest with only “negative” symptoms producing acute onset, focal neurologic deficits. A history of clonic jerks or tonic posturing at onset, a known past history of seizures, and electroencephalogram findings may be helpful. Imaging is required in all new cases of seizure with persisting Todd’s paresis because stroke in children is often associated with seizures at onset.

INFECTION
Life-threatening and treatable brain infections, including bacterial meningitis and herpes encephalitis, can be mistaken for stroke. However, symptom onset in primary central nervous system infection is typically more gradual and less focal with fever as a consistent feature. Children with bacterial meningitis are at risk for both venous and arterial stroke.

DEMYELINATION
Acute disseminated encephalomyelitis, clinically isolated syndrome, multiple sclerosis, and other demyelinating conditions can present

</table>
with acute focal neurologic deficits. Symptom onset and initial progression is more gradual (typically hours or days) compared with stroke onset (minutes). Multifocal deficits, or concurrent encephalopathy in the case of acute disseminated encephalomyelitis, would decrease the probability of stroke.

**HYPOGLYCEMIA**
Acute lowering of blood glucose levels can produce focal deficits mimicking stroke. New-onset hypoglycemia in otherwise healthy children is rare, but predisposing conditions include insulin-dependent diabetes, adrenal insufficiency, steroid withdrawal, and ketogenic diet.

**GLOBAL HYPOXIC–ISCHEMIC ENCEPHALOPATHY**
Generalized decreases in cerebral perfusion can produce focal areas of watershed brain infarction which can be asymmetric and mimic stroke. Watershed ischemic injury should be accompanied by recognized hypotension or conditions predisposing to low cerebral perfusion such as sepsis, dehydration, or cardiac dysfunction. Clinical presentations would involve more generalized and bilateral cerebral dysfunction compared to stroke and the anatomic location of the infarct is in typical bilateral watershed zones rather than a single arterial territory.

**HYPERTENSIVE ENCEPHALOPATHY**
The posterior reversible leukoencephalopathy syndrome is seen in children with hypertension, often in the context of an acute rise in blood pressure. Posterior regions are selectively involved, possibly resulting in symptoms of bilateral cortical visual dysfunction in addition to encephalopathy and seizures.

**INBORN ERRORS OF METABOLISM**
Mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke-like episodes (MELAS; see Chapter 598.2) are the classic examples, though other mitochondrial disease can mimic stroke. Features favoring MELAS would include a history of developmental regression, posterior (and often bilateral) lesions not respecting vascular territories on MRI, and elevated serum or cerebrospinal fluid lactate (MR spectroscopy). In contrast to these types of “metabolic infarction,” children with Fabry disease (see Chapter 613.6) and homocystinuria (see Chapter 85.4) are at risk of true ischemic stroke.

**VESTIBULOPATHY/ATAXIA**
Acute onset vertigo and/or ataxia can be confused with brainstem or cerebellar stroke. Simple bedside tests of vestibular function with otherwise intact brainstem functions are reassuring. This differential diagnosis includes acute vestibular neuropathy, viral labyrinthitis, and the benign paroxysmal vertigos as well as acute cerebellar ataxia and episodic ataxias.

**CHANNELOPATHIES**
An increasing number of nervous system ion channel mutations are described that feature sudden focal neurological deficits thereby mimicking stroke. These include the migraine syndromes mentioned above as well as a growing list of episodic ataxias. A strong family history raises suspicion but most require additional investigation.

**ALTERNATING HEMIPLEGIA OF CHILDHOOD**
Alternating hemiplegia of childhood typically presents in infancy with acute intermittent episodes of hemiplegia that alternate from 1 side of the body to the other. The hemiplegia persists for minutes to weeks and then resolves spontaneously. Choreoathetosis and dystonic movements are commonly observed in the hemiparetic extremity. Signs spontaneously regress with sleep but recur with awakening. Neuroimaging including MRA should be completed to exclude moyamoya disease. Alternating hemiplegia of childhood is linked to mutations in the \textit{ATP1A3} gene.
Autoimmune-mediated inflammatory brain diseases are recognized as an etiology for neurologic and neuropsychiatric symptoms in children and adults and include primary central nervous system (CNS) vasculitis, secondary CNS vasculitis, and autoimmune encephalitis (Fig. 602-1; see Chapter 598.4).

Primary angiitis of the CNS (PACNS) is recognized as the underlying etiology of a broad spectrum of neurologic and psychiatric symptoms in children. Criteria characteristic of childhood CNS vasculitis (cPACNS) include (1) newly acquired focal and/or diffuse neurologic deficits and/or psychiatric symptoms in a child 18 yr of age or younger, plus (2) angiographic and/or histologic evidence of vasculitis in the absence of (3) a systemic underlying condition known to cause or mimic the findings. Two broad categories of cPACNS are recognized based on the predominant vessel size affected: large/medium-vessel cPACNS and small-vessel cPACNS. Large/medium-vessel cPACNS is diagnosed on angiography demonstrating features of vessel wall inflammation, wall swelling and edema, and resulting luminal stenosis. Based on the clinical course and the corresponding distribution of vessel stenosis within the vascular tree of the CNS, children with large/medium-vessel cPACNS are classified as a monophasic, nonprogressive (NPcPACNS) or a progressive subtype (PcPACNS). The latter is characterized by chronic, progressive vessel wall inflammation affecting both proximal and distal vessel segments in 1 or both hemispheres. In contrast, NPcPACNS is a monophasic illness; vessel inflammation occurs in a characteristic distribution and is limited to the proximal vessel segments of the anterior and/or middle cerebral artery and/or distal internal carotid artery of 1 hemisphere. Small vessel cPACNS (SVcPACNS) is considered a progressive illness; the diagnosis is confirmed on brain biopsies because angiography is normal.

Secondary childhood CNS vasculitis can affect all cerebral vessel segments and can occur in the context of infections, rheumatic or other inflammatory conditions or as a result of systemic or local vascular irritation (Table 602-1). The neuropsychiatric manifestations of secondary CNS vasculitis are the same as those of primary CNS vasculitis. Secondary CNS vasculitis is distinguished from primary CNS vasculitis largely by the non-CNS manifestations of the underlying systemic vasculitic disease.

**EPIDEMIOLOGY**

The incidence and prevalence of primary CNS vasculitis is undetermined. In the past, the majority of children have been diagnosed at autopsy. Increased physician awareness, improved diagnostic markers, sensitive neuroimaging techniques, and brain biopsies have led to dramatically increased recognition and decreased mortality. Exploring the epidemiology of primary CNS vasculitis remains a challenge: the disease has many names including isolated angiitis of the CNS, transient cerebral angiitis, postvaricella angiopathy, and focal cerebral arteriopathy. Furthermore, children are frequently diagnosed with their presenting clinical phenotype, such as stroke, movement disorder, hallucination, or cognitive decline. Within clinical phenotypes, such as arterial ischemic stroke or status epilepticus in children without preexisting epilepsy, cPACNS should be considered an important etiology.

**CLINICAL MANIFESTATIONS**

Recognition of childhood CNS vasculitis requires a very high level of suspicion; any neurologic or psychiatric presentation can be the result
of an underlying CNS vasculitis. The clinical phenotype may provide clues to the size of the primarily affected vessel segments and resulting cPACNS subtype: the majority of children with large/medium cPACNS present with arterial ischemic stroke features. Focal neurologic deficits, such as hemiparesis, facial droop, aphasia or any other distinct gross or fine motor deficits, may be the result of large vessel inflammation causing stenosis and decreased blood supply to the specific functional areas of the brain. Initially, these focal deficits wax and wane; they may even briefly resolve without therapeutic intervention and can therefore be easily overlooked. Headaches are a symptom of vascular disease in general and are commonly reported in cPACNS. New onset of vascular-type (e.g., migraine) headaches in children without any family history of migraine can serve as a diagnostic clue. Cognitive dysfunction in cPACNS often includes loss of higher executive function, concentration difficulties, learning and memory problems, atypical behavior or personality changes, and loss of social and emotional control. Seizures are a hallmark of SvPACNS, as more than 80% of children with SvPACNS present with seizures; all seizure types are seen. Often there is a disconnection between the clinical presentation and the child’s electroencephalogram findings. In many centers, refractory status epilepticus is increasingly recognized as the presenting phenotype of SvPACNS. Optic neuritis and spinal cord disease are also recognized in SvPACNS.

Constitutional features of fever or fatigue may point toward an underlying systemic illness causing a secondary CNS vasculitis. All children with suspected or confirmed CNS vasculitis require a careful assessment for a systemic illness.

**DIAGNOSIS**

The first step is considering vasculitis as a possible underlying etiology of newly acquired neurologic deficits and/or psychiatric symptoms (Table 602-2). The likelihood of CNS vasculitis in general and a specific subtype of CNS vasculitis in particular depends on the demographic characteristics of the patient, the CNS and non-CNS features of the clinical presentation, the preceding symptoms, and the mode of onset of the disease. SvPACNS is more commonly seen in girls of all ages, whereas large/medium cPACNS has a clear male preponderance. Seizures are a hallmark of SvPACNS, whereas strokes often reflect large/medium-vessel inflammation. Laboratory markers of vasculitis typically include C-reactive protein, erythrocyte sedimentation rate, and complete blood counts. But inflammatory markers lack sensitivity and specificity in cPACNS, particularly when the CNS is involved in isolation. More than 50% of children with large/medium-vessel cPACNS have normal inflammatory markers at diagnosis. In contrast, the majority of children with SvPACNS present with mild-moderately raised markers. Von Willebrand factor antigen, an endothelial cell–derived protein, is a proposed biomarker of vasculitis correlating closely with disease activity in cPACNS. It may be of particular importance for distinguishing SvPACNS from demyelinating diseases. Cerebrospinal fluid (CSF) analysis is abnormal in up to 90% of SvPACNS patients and less than half of large/medium-vessel cPACNS. Within the latter group, children with the progressive subtype have a higher likelihood of presenting with abnormal CSF findings, including high opening pressure, raised CSF cell count, typically with lymphocyte predominance, and raised CSF protein. Oligoclonal bands are seen in 20% of children with SvPACNS. They are rarely seen in other subtypes. Autoimmune encephalitis (see Chapter 598.4) is one of the key differential diagnoses of SvPACNS.

Neuroimaging is a valuable diagnostic modality for cPACNS. Parenchymal lesions may be inflammatory or ischemic in nature and are best viewed on MRI including T2/fluid attenuated inversion recovery (FLAIR) sequences and diffusion-weighted images (DWI) (Fig. 602-2). CNS lesions in children with large/medium-vessel cPACNS are predominantly ischemic in nature and restricted to large vascular territories. In contrast, MRI lesions in children with SvPACNS are not restricted to major vascular territories; lesions are primarily inflammatory and may enhance with contrast. In this subtype, focal or
generalized meningeal enhancement is commonly seen if children are imaged prior to immunosuppressive therapy. Spinal cord parenchymal imaging is challenging; defining the nature of lesions is often difficult. Evidence of vessel stenosis confirms the diagnosis in large/medium-vessel cPACNS subtypes; brain biopsies are not required. Important information about the disease activity can be obtained from post–gadolinium contrast studies of the vascular wall. The vessel wall of an inflamed cerebral vessel in active large/medium-vessel cPACNS subtypes is thickened and enhances contrast. Conventional angiography when compared to MR angiography has a higher sensitivity in detecting vessel stenosis in the distal vessel segments, the posterior circulation, and in very young children. Vessel wall imaging is often normal in children with SVcPACNS, sometimes mandating an elective brain biopsy to definitively make the diagnosis. Studies of regional blood flow or therapeutic trials of antiinflammatory or immunosuppressive agents are nonsurgical alternatives that do not afford specific diagnostic information. Biopsies should target low-risk, nonfunctional areas identified on MRI. In the appropriate clinical context, nonlesional biopsies have a high yield for confirming the diagnosis of SVcPACNS. Characteristic findings in SVcPACNS include an intramural and/or perivascular mononuclear infiltrate, evidence of endothelial activation, and reactive astrocyte activation. Gliosis and perivascular demyelination are hallmarks of long-standing disease. Findings typically seen in adult PACNS, including granulomas or vessel wall necrosis, are rarely seen in children with SVcPACNS. In children, the diagnostic yield of brain biopsies is 70%. Biopsy-related complications are rarely seen.

CSF, cerebrospinal fluid; PCNSV, primary CNS vasculitis; RCVS, reversible cerebral vasoconstriction syndrome.

Disorders that may be seen in adolescents and young adults that produce the reversible vasoconstriction syndrome must also be considered. These include migraine, drug-induced vasospasm, and postpartum angiopathy. Differentiating vasculitis is important for therapy and prognosis (Table 602-3).

**TREATMENT**

Corticosteroids are the mainstay of acute immunosuppressive management of cPACNS. Usually IV pulse therapy is initially given. Antithrombotic therapy is equally important, particularly in large/medium-vessel cPACNS subtypes, because children are at high risk for recurrent ischemic events. For the distinct cPACNS subtypes, different treatment regimens should be considered. Nonprogressive cPACNS is a monophasic inflammatory attack with the highest risk of poor neurologic outcome. Vessel wall inflammation causes severe proximal stenosis and a high restroke risk. High-dose corticosteroid pulses are commonly given followed by a 6-12 wk course of oral steroids at tapering doses. Second-line immunosuppressive agents are uncommonly used. All children require antithrombotic therapy. No unifying regimen exists. Many centers initially use low-molecular-weight heparin followed by long-term antiplatelet therapy. When reimaged at 3 mo follow-up, children should have stable or improved vessel disease, no newly affected vessel segments, and no evidence of contrast wall enhancement. At this point the immunosuppressive therapy is commonly discontinued and children are only kept on antiplatelet agents.

Progressive cPACNS and SVC PACNS are considered chronic progressive vasculitis subtypes requiring a prolonged course of combination immunosuppression. High-dose corticosteroids are initially used followed by long-term oral corticosteroids with slow taper. Many centers use an induction-maintenance protocol adding IV cyclophosphamide to the corticosteroids as the induction medication, followed by mycophenolate mofetil or other oral second-line agents during maintenance therapy. Symptomatic therapy is essential including anticonvulsants or psychotropic medication if required. Supportive therapy includes bone protection with calcium and vitamin D, prophylaxis against pneumocystis pneumonia, and gastric mucosal protection as required.

**PROGNOSIS**

The mortality rate of cPACNS has significantly improved. Some treatment protocols for SVC PACNS report a good outcome, defined as no functional neurologic deficits in two-thirds of children. Children presenting with status epilepticus and SVC PACNS have the poorest cognitive outcome.

Bibliography

Infection of the central nervous system (CNS) is the most common cause of fever associated with signs and symptoms of CNS disease in children. Many microorganisms can cause infection. Nonetheless, specific pathogens are identifiable and are influenced by the age and immune status of the host and the epidemiology of the pathogen. In general, viral infections of the CNS are much more common than bacterial infections, which, in turn, are more common than fungal and parasitic infections. Infections caused by rickettsiae (Rocky Mountain spotted fever, *Ehrlichia*) are relatively uncommon but assume important roles under certain epidemiologic circumstances. *Mycoplasma* spp. can also cause infections of the CNS, although their precise contribution is often difficult to determine.

Regardless of etiology, most patients with CNS infection have similar clinical manifestations. **Common symptoms** include headache, nausea, vomiting, anorexia, restlessness, altered state of consciousness, and irritability; most of these symptoms are nonspecific. **Common signs** of CNS infection, in addition to fever, include photophobia, neck pain and rigidity, obtundation, stupor, coma, seizures, and focal neurologic deficits. The severity and constellation of signs are determined by the specific pathogen, the host, and the area of the CNS affected.

Infection of the CNS may be diffuse or focal. Meningitis and encephalitis are examples of diffuse infection. Meningitis implies primary involvement of the meninges, whereas encephalitis indicates brain parenchymal involvement. Because these anatomic boundaries are often not distinct, many patients have evidence of both meningeal and parenchymal involvement and should be considered to have meningoencephalitis. Brain abscess is the best example of a focal infection of the CNS. The neurologic expression of this infection is determined by the site and extent of the abscess(es) (see Chapter 604).

The diagnosis of diffuse CNS infections depends on examination of cerebrospinal fluid (CSF) obtained by lumbar puncture (LP). Table 603-1 provides an overview of the expected CSF abnormalities with various CNS disorders.

**COMMON FORMS OF MENINGITIS**

- **Acute bacterial meningitis**
  - Usually elevated (100-300)
  - 100-10,000 or more; usually 300-2,000; PMNs predominate
  - Usually 100-500
  - Decreased, usually <40 (or <50% serum glucose)
  - Normal or decreased
  - Organisms usually seen on Gram stain and recovered by culture

- **Partially treated bacterial meningitis**
  - Normal or elevated
  - 5-10,000; PMNs usual but mononuclear cells may predominate if pretreated for extended period of time
  - Usually 100-500
  - Decreased, usually <40 (or <50% serum glucose)
  - Organisms may be seen on Gram stain
  - Pretreatment may render CSF sterile. Antigen may be detected by agglutination test

- **Viral meningitis or meningoencephalitis**
  - Normal or slightly elevated (80-150)
  - Rarely >1,000 cells. Eastern equine encephalitis and lymphocytic choriomeningitis may have cell counts of several thousand. PMNs early but mononuclear cells predominate through most of the course
  - Usually 50-200
  - Generally normal; may be decreased to <40 in some viral diseases, particularly mumps (15-20% of cases)
  - HSV encephalitis is suggested by focal seizures or by focal findings on CT or MRI scans or EEG. Enteroviruses and HSV infrequently recovered from CSF. HSV and enteroviruses may be detected by PCR of CSF

**UNCOMMON FORMS OF MENINGITIS**

- **Tuberculous meningitis**
  - Usually elevated
  - 10-500; PMNs early, but lymphocytes predominate through most of the course
  - 100-3,000, may be higher in presence of block
  - <50 in most cases; decreases with time if treatment is not provided
  - Acid-fast organisms almost never seen on smear. Organisms may be recovered in culture of large volumes of CSF. *Mycobacterium tuberculosis* may be detected by PCR of CSF

- **Fungal meningitis**
  - Usually elevated
  - 5-500; PMNs early but mononuclear cells predominate through most of the course
  - Cryptococcal meningitis may have no cellular inflammatory response
  - 25-500
  - <50; decreases with time if treatment is not provided
  - Budding yeast may be seen. Organisms may be recovered in culture. Cryptococcal antigen (CSF and serum) may be positive in cryptococcal infection

- **Syphilis (acute) and leptospirosis**
  - Usually elevated
  - 50-500; lymphocytes predominate
  - 10-500
  - Normal
  - Usually normal
  - Positive CSF serology. Spirochetes not demonstrable by usual techniques of smear or culture; dark-field examination may be positive

- **Amebic (Naegleria) meningoencephalitis**
  - Elevated
  - 1,000-10,000 or more; PMNs predominate
  - 50-500
  - Normal or slightly decreased
  - Mobile amebas may be seen by hanging-drop examination of CSF at room temperature

**BRAIN ABSCESES AND PARAMENINGEAL FOCUS**

- **Brain abscess**
  - Usually elevated (100-500)
  - 5-200; CSF rarely acellular; lymphocytes predominate; if abscess ruptures into ventricle, PMNs predominate and cell count may reach >100,000
  - 75-500
  - Normal unless abscess ruptures into ventricular system
  - No organisms on smear or culture unless abscess ruptures into ventricular system

- **Subdural empyema**
  - Usually elevated (100-500)
  - 100-5,000; PMNs predominate
  - 100-500
  - Normal
  - No organisms on smear or culture of CSF unless meningitis also present; organisms found on tap of subdural fluid

- **Cerebral epidural abscess**
  - Normal to slightly elevated
  - 10-500; lymphocytes predominate
  - 10-100; lymphocytes predominate
  - 100-1,000 or more; PMNs predominate
  - 50-200
  - Normal
  - Normal
  - Normal
  - No organisms on smear or culture of CSF

- **Spinal epidural abscess**
  - Usually low, with spinal block
  - 100-1,000 or more; PMNs predominate
  - 50-100
  - Normal
  - Normal
  - Normal
  - Epithelial cells may be seen within CSF by use of polarized light in some children with dermoids

Continued
603.1 Acute Bacterial Meningitis Beyond the Neonatal Period
Charles G. Prober and Roshni Mathew

Bacterial meningitis is one of the most potentially serious infections occurring in infants and older children. This infection is associated with a high rate of acute complications and risk of long-term morbidity. The incidence of bacterial meningitis is sufficiently high in febrile infants that it should be included in the differential diagnosis of those with altered mental status and other evidence of neurologic dysfunction.

ETIOLOGY

The most common causes of bacterial meningitis in children older than 1 mo of age in the United States are Streptococcus pneumoniae and Neisseria meningitidis. Bacterial meningitis caused by S. pneumoniae and Haemophilus influenzae type b has become much less common in developed countries since the introduction of universal immunization against these pathogens beginning at 2 mo of age. Demonstrating the importance of vaccination, invasive H. influenzae disease was reported in Minnesota in 2008 in 5 children with no relationship to one another and who were partially or not immunized. It is the largest number of children with invasive H. influenzae in Minnesota since 1992. Infection caused by S. pneumoniae or H. influenzae type b must be considered in incompletely vaccinated individuals or those in developing countries. Those with certain underlying immunologic (HIV infection, immunoglobulin [Ig] G subclass deficiency) or anatomic (spleen dysfunction, cochlear defects or implants) disorders also may be at increased risk of infection caused by these bacteria.

Alterations of host defense resulting from anatomic defects or immune deficits also increase the risk of meningitis from less-common pathogens such as Pseudomonas aeruginosa, Staphylococcus aureus, coagulase-negative staphylococci, Salmonella spp., anaerobes, and Listeria monocytogenes.

EPIDEMIOLOGY

A major risk factor for meningitis is the lack of immunity to specific pathogens associated with young age. Additional risks include recent colonization with pathogenic bacteria, close contact (household, daycare centers, college dormitories, military barracks) with individuals having invasive disease caused by N. meningitidis or H. influenzae type b, crowding, poverty, black or Native American race, and male gender. The mode of transmission is probably person-to-person contact through respiratory tract secretions or droplets. The risk of meningitis is increased among infants and young children with occult bacteremia; the odds ratio is greater for meningococcus (85 times) and H. influenzae type b (12 times) relative to that for pneumococcus.

Specific host defense defects as a result of altered immunoglobulin production in response to encapsulated pathogens may be responsible for the increased risk of bacterial meningitis in Native Americans and Eskimos. Defects of the complement system (C5-C8) are associated with recurrent meningococcal infection, and defects of the properdin system are associated with a significant risk of lethal meningococcal disease. Splenic dysfunction (sickle cell anemia) or asplenia (caused by trauma or congenital defect) is associated with an increased risk of pneumococcal, H. influenzae type b (to some extent), and, rarely, meningococcal sepsis and meningitis. T-lymphocyte defects (congenital or acquired by chemotherapy, AIDS, or malignancy) are associated with an increased risk of L. monocytogenes infections of the CNS.

A congenital or acquired CSF leak across a mucocutaneous barrier, such as a lumbar dural sinus, cranial or midline facial defects (cerebroform plate), and middle ear (stapedial foot plate) or inner ear fistulas (oval window, internal auditory canal, cochlear aqueduct), or CSF leakage through a rupture of the meninges as a result of a basal skull fracture into the cerebroform plate or paranasal sinus, is associated with an increased risk of pneumococcal meningitis. The risk of bacterial meningitis, caused by S. pneumoniae, in children with cochlear implants, used for the treatment of hearing loss, is more than 30 times the risk in the general U.S. population. Lumbosacral dural sinus and meningomyelocele are associated with staphylococcal, anaerobic, and Gram-negative enteric bacterial meningitis. CSF shunt infections increase the risk of meningitis caused by staphylococci (especially coagulase-negative species) and other low-virulence bacteria that typically colonize the skin.

Streptococcus pneumoniae

See Chapter 182.

The 7-valent pneumococcal protein polysaccharide conjugate vaccine (PCV7) was introduced into the routine vaccination schedule in 2000 and contained the serotypes 4, 6B, 9V, 14, 18C, 19F, and 23F. These serotypes caused most of the invasive pneumococcal infections in the United States at that time. The vaccine led to a dramatic decrease in rates of invasive pneumococcal disease. However, an increase in invasive disease caused by serotypes not contained in the original vaccine, such as serotype 19A, was observed. As a result, a 13-valent pneumococcal polysaccharide-protein conjugate vaccine (PCV13) was licensed in the United States in February 2010. PCV13 contains the serotypes in PCV7 plus serotypes 1, 3, 5, 6A, 7F, and 19A. This vaccine is recommended for routine administration to all children 2-59 mo of age. The PCV13 vaccine is given as a 4-dose series at 2, 4, 6, and 12-15 mo of age. The incidence of invasive pneumococcal infections

peaks in the 1st 2 yr of life, reaching rates of 228 per 100,000 in children 6-12 mo of age. Children with anatomic or functional asplenia secondary to sickle cell disease and those infected with HIV have infection rates that are 20-100-fold higher than in those of healthy children in the 1st 5 yr of life. Additional risk factors for contracting pneumococcal meningitis include otitis media, sinusitis, pneumonia, CSFotorrhrea or rhinorrhea, the presence of a cochlear implant, and chronic graft–versus-host disease following bone marrow transplantation.

**Neisseria meningitidis**

See Chapter 191.

Five serogroups of meningococcus—A, B, C, Y, and W-135—are responsible for disease. Meningococcal meningitis may be sporadic or may occur in epidemics. In the United States, serogroups B, C, and Y each account for approximately 30% of cases, although serogroup distribution varies by location and time. Epidemic disease, especially in developing countries, is usually caused by serogroup A. Cases occur throughout the year but may be more common in the winter and spring following influenza virus infections. Nasopharyngeal carriage of *N. meningitidis* occurs in 1-15% of adults. Colonization may last weeks to months; recent colonization places nonimmune younger children at greatest risk for meningitis. The incidence of disease occurring in association with an index case in the family is 1%, a rate that is 1,000-fold the risk in the general population. The risk of secondary cases occurring in contacts at daycare centers is approximately 1 in 1,000. Most infections of children are acquired from a contact in a daycare facility; a colonized adult family member, or an ill patient with meningococcal disease. Children younger than 5 yr have the highest rates of meningococcal infection. A second peak in incidence occurs in persons between 15 and 24 yr of age. College freshmen living in dormitories have an increased incidence of infection compared to non-college-attending, age-matched controls.

The Centers for Disease Control and Prevention (CDC) recommends vaccination against meningococcus (types A, C, W, and Y) with 1 dose of a quadrivalent conjugate meningococcal vaccine between the ages of 11 and 12 yr and for persons 2 mo to 18 yr who are at increased risk for meningococcal disease. The CDC also has specific recommendations for meningococcal vaccination of infants at high risk of meningococcal infection as a consequence of complement pathway deficiencies. College freshmen living in dormitories who have not been previously vaccinated should also be vaccinated.

**Haemophilus influenzae Type B**

See Chapter 194.

Before universal *H. influenzae* type b vaccination in the United States, approximately 70% of cases of bacterial meningitis occurring in the 1st 5 yr of life were caused by this pathogen. Invasive infections occurred primarily in infants 2 mo to 2 yr of age; peak incidence was at 6-9 mo of age, and 50% of cases occurred in the 1st yr of life. The risk to children was markedly increased among family or daycare center contacts of patients with *H. influenzae* type b disease. Incompletely vaccinated individuals, those in underdeveloped countries who are not vaccinated, and those with blunted immunologic responses to vaccine (such as children with HIV infection) remain at risk for *H. influenzae* type b meningitis.

**PATHOLOGY AND PATHOPHYSIOLOGY**

A meningeal purulent exudate of varying thickness may be distributed around the cerebral veins, venous sinuses, convexity of the brain, and cerebellum, and in the sulci, sylvian fissures, basal cisterns, and spinal cord. Ventriculitis with bacteria and inflammatory cells in ventricular fluid may be present (more often in neonates), as may subdural effusions and, rarely, empyema. Perivascular inflammatory infiltrates also may be present, and the ependymal membrane may be disrupted. Vascular and parenchymal cerebral changes characterized by polymorphonuclear infiltrates extending to the subintimal region of the small arteries and veins, vasculitis, thrombosis of small cortical veins, occlusion of major venous sinuses, necrotizing arteritis producing subarachnoid hemorrhage, and, rarely, cerebral cortical necrosis in the absence of identifiable thrombosis have been described at autopsy. Cerebral infarction, resulting from vascular occlusion because of inflammation, vasospasm, and thrombosis, is a frequent sequela. Infarct size ranges from microscopic to involvement of an entire hemisphere.

Inflammation of spinal nerves and roots produces meningeal signs, and inflammation of the cranial nerves produces cranial neuropathies of optic, oculomotor, facial, and auditory nerves. Increased intracranial pressure (ICP) also produces oculomotor nerve palsy because of the presence of temporal lobe compression of the nerve during tentorial herniation. Abducens nerve palsy may be a nonlocalizing sign of elevated ICP.

Increased ICP is a result of cell death (cystotocic cerebral edema), cytokine-induced increased capillary vascular permeability (vasogenic cerebral edema), and, possibly, increased hydrostatic pressure (interstitial cerebral edema) after obstructed reabsorption of CSF in the arachnoid villi or obstruction of the flow of fluid from the ventricles. ICP may exceed 300 mm H2O cerebral perfusion may be further compromised if the cerebral perfusion pressure (mean arterial pressure minus ICP) is <50 cm H2O as a result of systemic hypertension with reduced cerebral blood flow. The syndrome of inappropriate antidiuretic hormone secretion (SIADH) may produce excessive water retention and potentially increase the risk of elevated ICP (see Chapter 559). Hypotonicity of brain extracellular spaces may cause cystotic edema after cell swelling and lysis. Tentorial, falx, or cerebellar herniation does not usually occur because the increased ICP is transmitted to the entire subarachnoid space and there is little structural displacement. Furthermore, if the fontanelles are still patent, increased ICP is not always dissipated.

Hydrocephalus can occur as an acute complication of bacterial meningitis. It most often takes the form of a communicating hydrocephalus caused by adhesive thickening of the arachnoid villi around the cisterns at the base of the brain. Thus, there is interference with the normal resorption of CSF. Less often, obstructive hydrocephalus develops after fibrosis and gliosis of the aqueduct of Sylvius or the foramina of Magendie and Luschka.

Raised CSF protein levels are partly a result of increased vascular permeability of the blood–brain barrier and the loss of albumin-rich fluid from the capillaries and veins traversing the subdural space. Continued transudation may result in subdural effusions, usually found in the later phase of acute bacterial meningitis. Hypoglycorrachia (reduced CSF glucose levels) is attributable to decreased glucose transport by the cerebral tissue.

Damage to the cerebral cortex may be a result of the focal or diffuse effects of vascular occlusion (infarction, necrosis, lactic acidosis), hypoxia, bacterial invasion (cerebritis), toxic encephalopathy (bacterial toxins), elevated ICP, ventriculitis, and transudation (subdural effusions). These pathologic factors result in the clinical manifestations of impaired consciousness, seizures, cranial nerve deficits, motor and sensory deficits, and later psychomotor retardation.

**PATHOGENESIS**

Bacterial meningitis most commonly results from hematogenous dissemination of microorganisms from a distant site of infection; bacteremia usually precedes meningitis or occurs concomitantly. Bacterial colonization of the nasopharynx with a potentially pathogenic microorganism is the usual source of the bacteremia. There may be prolonged carriage of the colonizing organisms without disease or, more likely, rapid invasion after recent colonization. Prior or concurrent viral upper respiratory tract infection may enhance the pathogenicity of bacteria producing meningitis.

*N. meningitidis* and *H. influenzae* type b attach to mucosal epithelial cell receptors by pili. After attachment to epithelial cells, bacteria breach the mucosa and enter the circulation. *N. meningitidis* may be transported across the mucosal surface within a phagocytic vacuole after ingestion by the epithelial cell. Bacterial survival in the bloodstream is enhanced by large bacterial capsules that interfere with opsonic phagocytosis and are associated with increased virulence. Host-related developmental defects in bacterial opsonic phagocytosis also contribute to the bacteremia. In young, nonimmune hosts, the...
defect may be from an absence of preformed IgM or IgG antcapsular antibodies, whereas in immunodeficient patients, various deficiencies of components of the complement or properdin system may interfere with effective opsonic phagocytosis. Splenic dysfunction may also reduce opsonic phagocytosis by the reticuloendothelial system.

Bacteria gain entry to the CSF through the choroid plexus of the lateral ventricles and the meninges and then circulate to the extracebral CSF and subarachnoid space. Bacteria rapidly multiply because the CSF concentrations of complement and antibody are inadequate to contain bacterial proliferation. Chemotactic factors then incite a local inflammatory response characterized by polymorphonuclear cell infiltration. The presence of bacterial cell wall lipopolysaccharide (endotoxin) of Gram-negative bacteria (H. influenzae type b, N. meningitidis) and of pneumococcal cell wall components (teichoic acid, peptidoglycan) stimulates a marked inflammatory response, with local production of tumor necrosis factor, interleukin 1, prostaglandin E, and other inflammatory mediators. The subsequent inflammatory response is characterized by neutrophil infiltration, increased vascular permeability, alterations of the blood–brain barrier, and vascular thrombosis. Meningitis–associated brain injury is not simply caused by viable bacteria but occurs as a consequence of the host reaction to the inflammatory cascade initiated by bacterial components.

Rarely, meningitis may follow bacterial invasion from a contiguous focus of infection such as paranasal sinusitis, otitis media, mastoiditis, orbital cellulitis, or cranial or vertebral osteomyelitis or may occur after introduction of bacteria via penetrating cranial trauma, dermal sinus tracts, or meningomyeloceles.

**CLINICAL MANIFESTATIONS**

The onset of acute meningitis has 2 predominant patterns. The more dramatic and, fortunately, less common presentation is sudden onset with rapidly progressive manifestations of shock, purpura, disseminated intravascular coagulation, and reduced levels of consciousness often resulting in progression to coma or death within 24 hr. Much more frequent, meningitis is preceded by several days of fever accompanied by upper respiratory tract or gastrointestinal symptoms, followed by nonspecific signs of CNS infection, such as increasing lethargy and irritability.

The signs and symptoms of meningitis are related to the nonspecific findings associated with a systemic infection and to manifestations of meningeal irritation. Nonspecific findings include fever, anorexia and poor feeding, headache, symptoms of upper respiratory tract infection, myalgias, arthralgias, tachycardia, hypotension, and various cutaneous signs, such as petechiae, purpura, or an erythematous macular rash. Meningeal irritation is manifested as nuchal rigidity, back pain, Kernig sign (flexion of the hip 90 degrees with subsequent pain with extension of the leg), and Gradedinski sign (involuntary flexion of the knees and hips after passive flexion of the neck while supine). In children, particularly in those younger than 12-18 mo, Kernig and Gradedinski signs are not consistently present. Indeed fever, headache, and nuchal rigidity are present in only 40% of adults with bacterial meningitis. Increased ICP is suggested by headache, emesis, bulging fontanel or diastasis (widening) of the sutures, oculomotor (anisocoria, ptosis) or abducens nerve paralysis, hypertension with bradycardia, apnea or hyperventilation, decorticate or decerebrate posturing, stupor, coma, or signs of herniation. Papilledema is uncommon in uncomplicated meningitis and should suggest a more chronic process, such as the presence of an intracranial abscess, subdural empyema, or occlusion of a dural venous sinus. Focal neurologic signs usually are a result of vascular occlusion. Cranial neuropathies of the ocular, oculomotor, abducens, facial, and auditory nerves may also be the result of focal inflammation. Overall, approximately 10-20% of children with bacterial meningitis have focal neurologic signs.

**Seizures** (focal or generalized) caused by cerebritis, infarction, or electrolyte disturbances occur in 20-30% of patients with meningitis. Seizures that occur on presentation or within the 1st 4 days of onset are usually of no prognostic significance. Seizures that persist after the 4th day of illness and those that are difficult to treat may be associated with a poor prognosis.

**Alterations of mental status** are common among patients with meningitis and may be the consequence of increased ICP, cerebritis, or hypotension; manifestations include irritability, lethargy, stupor, obtundation, and coma. Comatose patients have a poor prognosis. Additional manifestations of meningitis include photophobia and tache cérébrale, which is elicited by stroking the skin with a blunt object and observing a raised red streak within 30-60 sec.

**DIAGNOSIS**

The diagnosis of acute pyogenic meningitis is confirmed by analysis of the CSF, which typically reveals microorganisms on Gram stain and culture, a neutrophilic pleocytosis, elevated protein, and reduced glucose concentrations (see Table 603-1). LP should be performed when bacterial meningitis is suspected. Contraindications for an immediate LP include (1) evidence of increased ICP (other than a bulging fontanel), such as 3rd or 6th cranial nerve palsy with a depressed level of consciousness, or hypertension and bradycardia with respiratory abnormalities (see Chapter 590); (2) severe cardiopulmonary compromise requiring prompt resuscitative measures for shock or in patients in whom positioning for the LP would further compromise cardiopulmonary function; and (3) infection of the skin overlying the site of the LP. Thrombocytopenia is a relative contraindication for LP. If an LP is delayed, empirical antibiotic therapy should be initiated. CT scanning for evidence of a brain abscess or increased ICP should not delay therapy. LP may be performed after increased ICP has been treated or a brain abscess has been excluded.

Blood cultures should be performed in all patients with suspected meningitis. Blood cultures reveal the responsible bacteria in up to 80-90% of cases of meningitis. Elevations of the C-reactive protein, erythrocyte sedimentation rate, and procalcitonin have been used to differentiate bacterial (usually elevated) from viral causes of meningitis.

**Lumbar Puncture**

See Chapter 590.

The CSF leukocyte count in bacterial meningitis usually is elevated to >1,000/mm³ and, typically, there is a neutrophilic predominance (75-95%). Turbid CSF is present when the CSF leukocyte count exceeds 200-400/mm³. Normal healthy neonates may have as many as 30 leucocytes/mm³ (usually <10), but older children without viral or bacterial meningitis have <5 leucocytes/mm³ in the CSF; in both age groups there is a predominance of lymphocytes or monocytes.

A CSF leukocyte count <250/mm³ may be present in as many as 20% of patients with acute bacterial meningitis; pleocytosis may be absent in patients with severe overwhelming sepsis and meningitis and is a poor prognostic sign. Pleocytosis with a lymphocyte predominance may be present during the early stage of acute bacterial meningitis; conversely, neutrophilic pleocytosis may be present in patients in the early stages of acute viral meningitis. The shift to lymphocytic-monocytic predominance in viral meningitis invariably occurs within 8-24 hr of the initial LP. The Gram stain is positive in 70-90% of patients with untreated bacterial meningitis.

A diagnostic conundrum in the evaluation of children with suspected bacterial meningitis is the analysis of CSF obtained from children already receiving antibiotic (usually oral) therapy. This is an important issue, because 25-50% of children being evaluated for bacterial meningitis are receiving oral antibiotics when their CSF is obtained. CSF obtained from children with bacterial meningitis, after the initiation of antibiotics, may be negative on Gram stain and culture. Pleocytosis with a predominance of neutrophils, elevated protein level, and a reduced concentration of CSF glucose usually persist for several days after the administration of appropriate intravenous antibiotics. Therefore, despite negative cultures, the presumptive diagnosis of bacterial meningitis can be made. Some clinicians test CSF for the presence of bacterial antigens if the child has been pretreated with antibiotics and the diagnosis of bacterial meningitis is in doubt. These tests have technical limitations. Polymerase chain reactions using broad-based bacterial 16S ribosomal RNA gene patterns may be useful in diagnosing the
cause of culture-negative meningitis because of prior antibiotic therapy or the presence of a nonculturable fastidious pathogen.

A traumatic LP may complicate the diagnosis of meningitis. Repeat LP at a higher interspace may produce less hemorrhagic fluid, but this fluid usually also contains red blood cells. Interpretation of CSF leukocytes and protein concentration are affected by LPs that are traumatic, although the Gram stain, culture, and glucose level may not be influenced. Although methods for correcting for the presence of red blood cells have been proposed, it is prudent to rely on the bacteriologic results rather than attempt to interpret the CSF leukocyte and protein results of a traumatic LP. Children with seizure, particularly those with fever associated status epilepticus do not have a CSF pleocytosis in the absence of CNS infection or inflammatory disease.

**Differential Diagnosis**

In addition to *S. pneumoniae, N. meningitidis, and H. influenzae* type b, many other microorganisms can cause generalized infection of the CNS with similar clinical manifestations. These organisms include less-typical bacteria, such as *Mycobacterium tuberculosis, Nocardia* spp., *Treponema pallidum* (syphilis), and *Borrelia burgdorferi* (Lyme disease); fungi, such as those endemic to specific geographic areas (*Coccidioides, Histoplasma, and Blastomyces*) and those responsible for infections in compromised hosts (*Candida, Cryptococcus, and Aspergillus*); parasites, such as *Toxoplasma gondii* and those that cause cisticercosis and, most frequently, viruses (see Chapter 603.2; Table 603-2). Focal infections of the CNS including brain abscess and parameningeal abscesses (subdural empyema, cranial and spinal epidural abscess) may also be confused with meningitis. In addition, noninfectious illnesses can cause generalized inflammation of the CNS. Relative to infections, these disorders are uncommon and include malignancy, collagen vascular syndromes, and exposure to toxins (Table 603-2).

Determining the specific cause of CNS infection is facilitated by careful examination of the CSF with specific stains (*Kinyoun carbol fuchsin for mycobacteria, India ink for fungi*), cytology, antigen detection (*Cryptococcus*, serology (syphilis, West Nile virus, arboviruses), viral culture (enterovirus), and polymerase chain reaction (herpes simplex, enterovirus, and others). Other potentially valuable diagnostic tests include blood cultures, CT or MRI of the brain, serologic tests, and, rarely, meningeal or brain biopsy. A unique MRI finding in patients suspected of CNS infection is pachymeningitis (Fig. 603-3). In addition to bacterial, tuberculous, or fungal infection (Fig. 603-1), the differential diagnosis also includes immune or inflammatory diseases such as Sweet syndrome, CNS vasculitis, sarcoidosis, lymphoma, and neonatal-onset multisystem inflammatory disease.

Acute viral meningoencephalitis is the most likely infection to be confused with bacterial meningitis (see Tables 603-2 and 603-3). Although, in general, children with viral meningoencephalitis appear less ill than those with bacterial meningitis, both types of infection have a spectrum of severity. Some children with bacterial meningitis may have relatively mild signs and symptoms, whereas some with viral meningoencephalitis may be critically ill. Although classic CSF profiles associated with bacterial vs viral infection tend to be distinct (see Table 603-1), specific test results may have considerable overlap.

**TREATMENT**

The therapeutic approach to patients with presumed bacterial meningitis depends on the nature of the initial manifestations of the illness. A child with rapidly progressing disease of less than 24 hr duration, in the absence of increased ICP, should receive antibiotics as soon as possible after an LP is performed. If there are signs of increased ICP or focal neurologic findings, antibiotics should be given without performing an LP and before obtaining a CT scan. Increased ICP should be treated simultaneously (see Chapter 68). Immediate treatment of associated multiple organ system failure, shock (see Chapter 70), and acute respiratory distress syndrome (see Chapter 71) is also indicated.

Patients who have a more protracted subacute course and become ill over a 4-7 day period should also be evaluated for signs of increased ICP and focal neurologic deficits. Unilateral headache, papilledema, and other signs of increased ICP suggest a focal lesion, such as a brain or epidural abscess, or subdural empyema. Under these circumstances, antibiotic therapy should be initiated before LP and CT scanning. If signs of increased ICP and/or focal neurologic signs are present, CT scanning should be performed first to determine the safety of performing an LP.

**Initial Antibiotic Therapy**

The initial (empirical) choice of therapy for meningitis in immunocompetent infants and children is primarily influenced by the antibiotic susceptibilities (Table 603-4) of *S. pneumoniae*. Selected antibiotics should achieve bactericidal levels in the CSF. Although there are substantial geographic differences in the frequency of resistance of *S. pneumoniae* to antibiotics, rates are increasing throughout the world. In the United States, 25-50% of strains of *S. pneumoniae* are currently resistant to penicillin; relative resistance (minimal inhibitory concentration = 0.1-1.0 µg/mL) is more common than high-level resistance (minimal inhibitory concentration = 2.0 µg/mL). Resistance to cefotaxime and ceftriaxone is also evident in up to 25% of isolates. In contrast, most strains of *N. meningitidis* are sensitive to penicillin and cephalosporins, although rare resistant isolates have been reported. Approximately 30-40% of isolates of *H. influenzae* type b produce β-lactamases and, therefore, are resistant to ampicillin. These β-lactamase-producing strains are sensitive to the extended-spectrum cephalosporins.

Based on the substantial rate of resistance of *S. pneumoniae* to β-lactam drugs, vancomycin (60 mg/kg/24 hr, given every 6 hr) is recommended as part of initial empirical therapy. Because of the efficacy of third-generation cephalosporins in the therapy of meningitis caused by sensitive *S. pneumoniae, N. meningitidis, and H. influenzae* type b, cefotaxime (300 mg/kg/24 hr, given every 6 hr) or ceftriaxone (100 mg/kg/24 hr administered once per day or 50 mg/kg/dose, given every 12 hr) should also be used in initial empirical therapy. Patients allergic to β-lactam antibiotics and >1 mo of age can be treated with chloramphenicol, 100 mg/kg/24 hr, given every 6 hr. Another option for patients with allergy to β-lactam antibiotics is a combination of vancomycin and rifampin. Alternatively, patients can be desensitized to the antibiotic (see Chapter 152).

If *L. monocytogenes* infection is suspected, as in young infants or those with a T-lymphocyte deficiency, ampicillin (200 mg/kg/24 hr, given every 6 hr) also should also be given because cephalosporins are inactive against *L. monocytogenes*. Intravenous trimethoprim-sulfamethoxazole is an alternative treatment for *L. monocytogenes*.

If a patient is immunocompromised and Gram-negative bacterial meningitis is suspected, initial therapy might include cefazidime and an aminoglycoside or meropenem.

**DURATION OF ANTIBIOTIC THERAPY**

Therapy for uncomplicated penicillin-sensitive *S. pneumoniae* meningitis should be for 10-14 days with a third-generation cephalosporin or intravenous penicillin (400,000 units/kg/24 hr, given every 4-6 hr). If the isolate is resistant to penicillin and the third-generation cephalosporin, therapy should be completed with vancomycin. Intravenous penicillin (300,000 units/kg/24 hr) for 5-7 days is the treatment of choice for uncomplicated *N. meningitidis* meningitis. Uncomplicated *H. influenzae* type b meningitis should be treated for 7-10 days. Patients who receive intravenous or oral antibiotics before LP and who do not have an identifiable pathogen, but do have evidence of an acute bacterial infection on the basis of their CSF profile, should continue to receive therapy with ceftriaxone or cefotaxime for 7-10 days. If focal signs are present or the child does not respond to treatment, a parameningeal focus may be present and a CT or MRI scan should be performed.

A routine repeat LP is not indicated in all patients with uncomplicated meningitis caused by antibiotic-sensitive *S. pneumoniae, N. meningitidis,* or *H. influenzae* type b. Repeat examination of CSF is indicated in some neonates, in all patients with Gram-negative bacillary meningitis, or in infection caused by a β-lactam–resistant *S. pneumoniae*. The CSF should be sterile within 24-48 hr of initiation of appropriate antibiotic therapy.

</table>

Meningitis caused by Escherichia coli or P. aeruginosa requires therapy with a third-generation cephalosporin active against the isolate in vitro. Most isolates of E. coli are sensitive to cefotaxime or ceftriaxone, and most isolates of P. aeruginosa are sensitive to ceftazidime. Gram-negative bacillary meningitis should be treated for 3 wk or for at least 2 wk after CSF sterilization, which may occur after 2-10 days of treatment.

Side effects of antibiotic therapy of meningitis include phlebitis, drug fever, rash, emesis, oral candidiasis, and diarrhea. Ceftriaxone may cause reversible gallbladder pseudolithiasis, detectable by abdominal ultrasonography. This is usually asymptomatic but may be associated with emesis and upper right quadrant pain.

**Corticosteroids**

Rapid killing of bacteria in the CSF effectively sterilizes the meningeal infection but releases toxic cell products after cell lysis (cell wall endotoxin) that precipitate the cytokine-mediated inflammatory cascade. The resultant edema formation and neutrophilic infiltration may produce additional neurologic injury with worsening of CNS signs and symptoms. Therefore, agents that limit production of inflammatory mediators may be of benefit to patients with bacterial meningitis.

Data support the use of intravenous dexamethasone, 0.15 mg/kg/dose given every 6 hr for 2 days, in the treatment of children older than 6 wk with acute bacterial meningitis caused by H. influenzae type b. Among children with meningitis caused by H. influenzae type b, corticosteroid recipients have a shorter duration of fever, lower CSF protein and lactate levels, and a reduction in sensorineural hearing loss. Data in children regarding benefits, if any, of corticosteroids in the treatment of meningitis caused by other bacteria are inconclusive. Early steroid treatment of adults with bacterial meningitis, especially those with pneumococcal meningitis, results in improved outcome.

Corticosteroids appear to have maximum benefit if given 1-2 hr before antibiotics are initiated. They also may be effective if given concurrently with or soon after the first dose of antibiotics. Complications of corticosteroids include gastrointestinal bleeding, hypertension, hyperglycemia, leukocytosis, and rebound fever after the last dose.

**Supportive Care**

Repeated medical and neurologic assessments of patients with bacterial meningitis are essential to identify early signs of cardiovascular, CNS, and metabolic complications. Pulse rate, blood pressure, and respiratory rate should be monitored frequently. Neurologic assessment, including pupillary reflexes, level of consciousness, motor strength, cranial nerve signs, and evaluation for seizures, should be made frequently in the 1st 72 hr, when the risk of neurologic complications is greatest. Important laboratory studies include an assessment of blood urea nitrogen; serum sodium, chloride, potassium, and bicarbonate levels; urine output and specific gravity; complete blood and platelet counts; and, in the presence of petechiae, purpura, or abnormal bleeding, measures of coagulation function (fibrinogen, prothrombin, and partial thromboplastin times).

Patients should initially receive nothing by mouth. If a patient is judged to be normovolemic, with normal blood pressure, intravenous fluid administration should be restricted to one-half to two-thirds of maintenance, or 800-1,000 mL/m²/24 hr, until it can be established that increased ICP or SIADH is not present. Fluid administration may be returned to normal (1,500-1,700 mL/m²/24 hr) when serum sodium levels are normal. Fluid restriction is not appropriate in the presence of systemic hypotension because reduced blood pressure may result in reduced cerebral perfusion pressure and CNS ischemia. Therefore, shock must be treated aggressively to prevent brain and other organ dysfunction (acute tubular necrosis, acute respiratory distress syndrome). Patients with shock, a markedly elevated ICP, coma, and refractory seizures require intensive monitoring with central arterial and venous access and frequent vital signs, necessitating admission to a pediatric intensive care unit. Patients with septic shock may require fluid resuscitation and therapy with vasoactive agents such as dopamine and epinephrine. The goal of such therapy in patients with meningitis is to avoid excessive increases in ICP without compromising blood flow and oxygen delivery to vital organs.

Neurologic complications include increased ICP with subsequent herniation, seizures, and an enlarging head circumference because of a subdural effusion or hydrocephalus. Signs of increased ICP should be treated emergently with endotracheal intubation and hyperventilation (to maintain the pCO₂ at approximately 25 mm Hg). In addition, intravenous furosemide (Lasix, 1 mg/kg) and mannitol (0.5-1.0 g/kg) osmotherapy may reduce ICP (see Chapter 68). Furosemide reduces brain swelling by venodilation and diuresis without increasing intracranial blood volume, whereas mannitol produces an osmolar gradient between the brain and plasma, thus shifting fluid from the CNS to the plasma, with subsequent excretion during an osmotic diuresis. Another approach to treating reductions of cerebral perfusion pressure caused by elevations of intracranial pressure is to increase systemic blood.
Seizures are common during the course of bacterial meningitis. Immediate therapy for seizures includes intravenous diazepam (0.1-0.2 mg/kg/dose) or lorazepam (0.05-0.10 mg/kg/dose), and careful attention paid to the risk of respiratory depression. Serum glucose, calcium, and sodium levels should be monitored. After immediate management of seizures, patients should receive phenytoin (15-20 mg/kg loading dose, 5 mg/kg/24 hr maintenance) to reduce the likelihood of recurrence. Phenytoin is preferred to phenobarbital because it produces less CNS depression and permits assessment of a patient's level of consciousness. Serum phenytoin levels should be monitored to maintain them in the therapeutic range (10-20 µg/mL).

### COMPLICATIONS
During the treatment of meningitis, acute CNS complications can include seizures, increased ICP, cranial nerve palsies, stroke,
cerebral or cerebellar herniation, and thrombosis of the dural venous sinuses.

Collections of fluid in the subdural space develop in 10-30% of patients with meningitis and are asymptomatic in 85-90% of patients. Subdural effusions are especially common in infants. Symptomatic subdural effusions may result in a bulging fontanel, diastasis of sutures, enlarging head circumference, emesis, seizures, fever, and abnormal results of cranial transillumination. CT or MRI scanning confirms the presence of a subdural effusion. In the presence of increased ICP or a depressed level of consciousness, symptomatic subdural effusion should be treated by aspiration through the open fontanel (see Chapters 68 and 590). Fever alone is not an indication for aspiration.

SIADH occurs in some patients with meningitis, resulting in hypotremia and reduced serum osmolality. This may exacerbate cerebral edema or result in hyponatremic seizures (see Chapter 55).

Fever associated with bacterial meningitis usually resolves within 5-7 days of the onset of therapy. Prolonged fever (>10 days) is noted in approximately 10% of patients. Prolonged fever is usually caused by intercurrent viral infection, nosocomial or secondary bacterial infection, thrombophlebitis, or drug reaction. Secondary fever refers to the recrudescence of elevated temperature after an afebrile interval. Nosocomial infections are especially important to consider in the evaluation of these patients. Pericarditis or arthritis may occur in patients being treated for meningitis, especially that caused by N. meningitidis. Involvement of these sites may result either from bacterial dissemination or from immune complex deposition. In general, infectious pericarditis or arthritis occurs earlier in the course of treatment than does immune-mediated disease.

Thrombocytosis, eosinophilia, and anemia may develop during therapy for meningitis. Anemia may be a result of hemolysis or bone marrow suppression. Disseminated intravascular coagulation is most often associated with the rapidly progressive pattern of presentation and is noted most commonly in patients with shock and purpura. The combination of endotoxemia and severe hypotension initiates the coagulation cascade; the coexistence of ongoing thrombosis may produce symmetric peripheral gangrene.

PROGNOSIS

Appropriate antibiotic therapy and supportive care have reduced the mortality of bacterial meningitis after the neonatal period to <10%.

The highest mortality rates are observed with pneumococcal meningitis. Severe neurodevelopmental sequelae may occur in 10-20% of patients recovering from bacterial meningitis, and as many as 50% have some, albeit subtle, neurobehavioral morbidity. The prognosis is poorest among infants younger than 6 mo and in those with high concentrations of bacteria/bacterial products in their CSF. Those with seizures occurring more than 4 days into therapy or with coma or focal neurologic signs on presentation have an increased risk of long-term sequelae. There does not appear to be a correlation between duration of symptoms before diagnosis of meningitis and outcome.

The most common neurologic sequelae include hearing loss, cognitive impairment, recurrent seizures, delay in acquisition of language, visual impairment, and behavioral problems. Sensorineural hearing loss is the most common sequela of bacterial meningitis and, usually, is already present at the time of initial presentation. It is a result of cochlear infection and occurs in as many as 30% of patients with pneumococcal meningitis, 10% with meningococcal, and 5-20% of those with H. influenzae type b meningitis. Hearing loss may also be caused by direct inflammation of the auditory nerve. All patients with bacterial meningitis should undergo careful audiologic assessment before or soon after discharge from the hospital. Frequent reassessment on an outpatient basis is indicated for patients who have a hearing deficit.

PREVENTION

Vaccination and antibiotic prophylaxis of susceptible at-risk contacts represent the 2 available means of reducing the likelihood of bacterial meningitis. The availability and application of each of these approaches depend on the specific infecting bacteria.

Neisseria meningitidis

Chromoprophylaxis is recommended for all close contacts of patients with meningococcal meningitis regardless of age or immunization status. Close contacts should be treated with rifampin 10 mg/kg/dose every 12 hr (maximum dose of 600 mg) for 2 days as soon as possible after identification of a case of suspected meningococcal meningitis or sepsis. Close contacts include household, daycare center, and nursery school contacts, and healthcare workers who have direct exposure to oral secretions (mouth-to-mouth resuscitation, suctioning, intubation). Exposed contacts should be treated immediately on suspicion of
Haemophilus influenzae Type B

Rifampin prophylaxis should be given to all household contacts of patients with invasive disease caused by *H. influenzae* type b, if any close family member younger than 48 mo has not been fully immunized or if an immunocompromised person, of any age, resides in the household. A household contact is one who lives in the residence of the index case or who has spent a minimum of 4 hr with the index case for at least 5 of the 7 days preceding the patient’s hospitalization. Family members should receive rifampin prophylaxis immediately after the diagnosis is suspected in the index case because >50% of secondary family cases occur in the 1st wk after the index patient has been hospitalized.

The dose of rifampin is 20 mg/kg/24 hr (maximum dose of 600 mg) given once each day for 4 days. Rifampin colors the urine and perspiration red-orange, stains contact lenses, and reduces the serum concentrations of some drugs, including oral contraceptives. Rifampin is contraindicated during pregnancy.

The most striking advance in the prevention of childhood bacterial meningitis followed the development and licensure of conjugated vaccines against *H. influenzae* type b. Three conjugate vaccines are licensed in the United States. Although each vaccine elicits different profiles of antibody response in infants immunized at 2-6 mo of age, all result in protective levels of antibody with an efficacy rate against invasive infections after primary series at 93%. Efficacy is not as consistent in Native American populations, a group recognized as having an especially high incidence of disease. All children should be immunized with *H. influenzae* type b conjugate vaccine beginning at 2 mo of age (see Chapter 172).

Streptococcus pneumoniae

Routine administration of conjugate vaccine against *S. pneumoniae* is recommended for children younger than 5 yr of age. The initial dose is given at about 2 mo of age. Children who are at high risk of invasive pneumococcal infections, including those with functional or anatomic asplenia and those with underlying immunodeficiency (such as infection with HIV, primary immunodeficiency, and those receiving immnosuppressive therapy) should also receive the vaccine.

Bibliography is available at Expert Consult.

### 603.2 Viral Meningoencephalitis

**Charles G. Prober and Nivedita S. Srinivas**

Viral meningoencephalitis is an acute inflammatory process involving the meninges and, to a variable degree, brain tissue. These infections are relatively common and may be caused by a number of different agents. The CSF is characterized by pleocytosis and the absence of microorganisms on Gram stain and routine bacterial culture. In most instances, the infections are self-limited. In some cases, substantial morbidity and mortality occur.

**ETIOLOGY**

**Enteroviruses** are the most common cause of viral meningoencephalitis. As of 2014, more than 70 serotypes of these small RNA viruses have been identified. The severity of infection caused by enteroviruses ranges from mild, self-limited illness with primarily meningeal involvement to severe encephalitis resulting in death or significant sequelae. Human enterovirus 68 has been associated with neurologic symptoms including flaccid paralysis. **Parechoviruses** may be an important cause of aseptic meningitis or encephalitis in infants. The clinical manifestations are similar to that of the enteroviruses with the exception of more severe MRI lesions of the cerebral cortex and at times an absence of a CSF pleocytosis.

**Arboviruses** are arthropod-borne agents, responsible for some cases of meningoencephalitis during summer months. Mosquitoes and ticks are the most common vectors, spreading disease to humans and other vertebrates, such as horses, after biting infected birds or small animals. Encephalitis in horses (“blind staggers”) may be the first indication of an incipient epidemic. Although rural exposure is most common, urban and suburban outbreaks also are frequent. The most common arboviruses responsible for CNS infection in the United States are West Nile virus (WNV), La Crosse, Powassan, and St. Louis encephalitis viruses (see Chapter 267). WNV made its appearance in the Western hemisphere in 1999. It has gradually made its way from the east to the west coast over successive summers. Cumulatively, from 1999 through 2008, a total of 47 states reported roughly 30,000 human infections caused by WNV. WNV may also be transmitted by blood transfusion, organ transplantation, or vertically across the placenta. Most children with WNV are either asymptomatic or have a nonspecific viral-like illness. Approximately 1% develop CNS disease; adults are more severely affected than children.

Several members of the *herpes family* of viruses can cause meningoencephalitis. Herpes simplex virus (HSV) type 1 is an important cause of severe, sporadic encephalitis in children and adults. Brain involvement usually is focal; progression to coma and death occurs in 70% of cases without antiviral therapy. Severe encephalitis with diffuse brain involvement is caused by HSV type 2 in neonates who usually contract the virus from their mothers at delivery. A mild transient form of meningoencephalitis may accompany genital herpes infection in sexually active adolescents; most of these infections are caused by HSV type 2. Varicella-zoster virus may cause CNS infection in close temporal relationship with chickenpox. The most common manifestation of CNS involvement is cerebellar ataxia, and the most severe is acute encephalitis. After primary infection, varicella-zoster virus becomes latent in spinal and cranial nerve roots and ganglia, expressing itself later as herpes zoster, sometimes with accompanying mild meningoencephalitis. Cytomegalovirus infection of the CNS may be part of congenital infection or disseminated disease in immunocompromised hosts, but it does not cause meningoencephalitis in normal infants and children. Epstein-Barr virus is associated with myriad CNS syndromes (see Chapter 254). Human herpes virus 6 can cause encephalitis, especially among immunocompromised hosts.

Mumps is a common pathogen in regions where mumps vaccine is not widely used. Mumps meningoencephalitis is mild, but deafness from damage of the 8th cranial nerve may be a sequela. Meningoencephalitis is caused occasionally by respiratory viruses (adenovirus, influenza virus, parainfluenza virus), rubella, rubella, or rubies; it may follow live virus vaccinations against polio, measles, mumps, or rubella.

**EPIDEMIOLOGY**

The epidemiologic pattern of viral meningoencephalitis is primarily determined by the prevalence of enteroviruses, the most common etiology. Infection with enteroviruses is spread directly from person to person.
Bibliography

to person, with a usual incubation period of 4-6 days. Most cases in temperate climates occur in the summer and fall. Epidemiologic considerations in aseptic meningitis due to agents other than enteroviruses also include season, geography (travel), climatic conditions, animal exposures, mosquito or tick bites, and factors related to the specific pathogen.

**PATHOGENESIS AND PATHOLOGY**

Neurologic disease is caused by direct invasion and destruction of neural tissues by actively multiplying viruses or by a host reaction to viral antigens. Tissue sections of the brain generally are characterized by meningeal congestion and mononuclear infiltration, perivascular cuffs of lymphocytes and plasma cells, some perivascular tissue necrosis with myelin breakdown, and neuronal disruption in various stages, including, ultimately, neuronophagia and endothelial proliferation or necrosis. A marked degree of demyelination with preservation of neurons and their axons is considered to represent predominantly “postinfectious” or an autoimmune encephalitis.

The cerebral cortex, especially the temporal lobe, is often severely affected by HSV; the arboviruses tend to affect the entire brain; rabies has a predilection for the basal structures. Involvement of the spinal cord, nerve roots, and peripheral nerves is variable.

**CLINICAL MANIFESTATIONS**

The progression and severity of disease are determined by the relative degree of meningeal and parenchymal involvement, which, in part, is determined by the specific etiology. The clinical course resulting from infection with the same pathogen varies widely. Some children may appear to be mildly affected initially, only to lapse into coma and die suddenly. In others, the illness may be ushered in by high fever, violent convulsions interspersed with bizarre movements, and hallucinations alternating with brief periods of clarity, followed by complete recovery.

The onset of illness is generally acute, although CNS signs and symptoms are often preceded by a nonspecific febrile illness of a few days’ duration. The presenting manifestations in older children are headache and hyperesthesia, and in infants, irritability and lethargy. Headache is most often frontal or generalized; adolescents frequently complain of retrobulbar pain. Fever, nausea and vomiting, photophobia, and pain in the neck, back, and legs are common. As body temperature increases, there may be mental dullness, progressing to stupor in combination with bizarre movements and convulsions. Focal neurologic signs may be stationary, progressive, or fluctuating. WNV and nonpolio enteroviruses may cause anterior horn cell injury and a flaccid paralysis. For those reported with WNV, encephalitis is more common than aseptic meningitis; acute flaccid paralysis may be noted in approximately 5% of patients. Nonetheless, many patients have a nonspecific febrile illness “West Nile fever” and may never seek medical attention. Loss of bowel and bladder control and unprovoked emotional outbursts may occur.

Exanthems often precede or accompany the CNS signs, especially with echoviruses, coxsackieviruses, varicella-zoster virus, measles, rubella, and, occasionally, WNV. Examination often reveals mucosal rigidity without significant localizing neurologic changes, at least at the onset.

Specific forms or complicating manifestations of CNS viral infection include Guillain-Barré syndrome, transverse myelitis, hemiplegia, and cerebellar ataxia.

**DIAGNOSIS**

The diagnosis of viral encephalitis is usually made on the basis of the clinical presentation of nonspecific prodrome followed by progressive CNS symptoms. The diagnosis is supported by examination of the CSF, which usually shows a mild mononuclear predominance (see Table 603–1). Other tests of potential value in the evaluation of patients with suspected viral meningoencephalitis include an electroencephalogram (EEG) and neuroimaging studies. The EEG typically shows diffuse slow-wave activity, usually without focal changes. Neuroimaging studies (CT or MRI) may show swelling of the brain parenchyma. Focal seizures or focal findings on EEG, CT, or MRI, especially involving the temporal lobes, suggest HSV encephalitis.

**Differential Diagnosis**

A number of clinical conditions that cause CNS inflammation mimic viral meningoencephalitis (see Table 603–2). The most important group of alternative infectious agents to consider is bacteria. Most children with acute bacterial meningeitis appear more critically ill than those with CNS viral infection. Parameningeal bacterial infections, such as brain abscess or subdural or epidural empyema, may have features similar to viral CNS infections. Infections caused by M. tuberculosis, T. pallidum (syphilis), B. burgdorferi (Lyme disease), and Bar tonella henselae, the bacillus associated with cat scratch disease, tend to result in indolent courses. Analysis of CSF and appropriate serologic tests are necessary to differentiate these various pathogens.

Infections caused by fungi, rickettsiae, mycoplasma, protozoa, and other parasites may also need to be included in the differential diagnosis. Consideration of these agents usually arises as a result of accompanying symptoms, geographic location of infection, or host immune factors.

Various noninfectious disorders may be associated with CNS inflammation and have manifestations overlapping with those associated with viral meningoencephalitis. Some of these disorders include malignancy, autoimmune diseases, intracranial hemorrhage, and exposure to certain drugs or toxins. Attention to history and other organ involvement usually allow elimination of these diagnostic possibilities. Autoimmune encephalitis owing to anti–N-methyl-D-aspartate receptor antibodies is an important cause of noninfectious encephalitis in children. Detection of these antibodies in the serum or CSF confirms this diagnosis. Acute disseminated encephalomyelitis may also initially be confused with encephalitis.

**Laboratory Findings**

The CSF contains from a few to several thousand cells per cubic millimeter. Early in the disease, the cells are often polymorphonuclear; later, mononuclear cells predominate. This change in cellular type is often demonstrated in CSF samples obtained as little as 8-12 hr apart. The protein concentration in CSF tends to be normal or slightly elevated, but concentrations may be very high if brain destruction is extensive, such as that accompanying HSV encephalitis. The glucose level is usually normal, although with certain viruses, for example, mumps, a substantial depression of CSF glucose concentrations may be observed. The CSF may be normal with parechovirus and in those who have encephalitis in the absence of meningeal involvement.

The success of isolating viruses from the CSF of children with viral meningoencephalitis is determined by the time in the clinical course that the specimen is obtained, the specific etiologic agent, whether the infection is a meningitis as opposed to a localized encephalitic process, and the skill of the diagnostic laboratory staff. Isolating a virus is most likely early in the illness, and the enteroviruses tend to be the easiest to isolate, although recovery of these agents from the CSF rarely exceeds 70%. To increase the likelihood of identifying the putative viral pathogen, specimens for culture should also be obtained from nasopharyngeal swabs, feces, and urine. Although isolating a virus from 1 or more of these sites does not prove causality, it is highly suggestive. Detection of viral DNA or RNA by polymerase chain reaction is the test of choice in the diagnosis of CNS infection caused by HSV, parechovirus and enteroviruses, respectively. CSF serology is the diagnostic test of choice for WNV.

A serum specimen should be obtained early in the course of illness and, if viral cultures are not diagnostic, again 2-3 wk later for serologic studies. Serologic methods are not practical for diagnosing CNS infections caused by the enteroviruses because there are too many serotypes. This approach may be useful, however, in confirming that a case is caused by a known circulating serotype. Serologic tests may also be of value in determining the etiology of nonenteroviral CNS infection, such as arboviral infection.
TREATMENT

With the exception of the use of acyclovir for HSV encephalitis (see Chapter 252), treatment of viral meningoencephalitis is supportive. Treatment of mild disease may require only symptomatic relief. Headache and hyperesthesia are treated with rest, non–aspirin-containing analgesics, and a reduction in room light, noise, and visitors. Acetaminophen is recommended for fever. Opioid agents and medications to reduce nausea may be useful, but if possible, their use in children should be minimized because they may induce misleading signs and symptoms. Intravenous fluids are occasionally necessary because of poor oral intake. More-severe disease may require hospitalization and intensive care.

It is important to monitor patients with severe encephalitis closely for convulsions, cerebral edema, inadequate respiratory exchange, disturbed fluid and electrolyte balance, aspiration and asphyxia, and cardiac or respiratory arrest of central origin. In patients with evidence of increased ICP, placement of a pressure transducer in the epidural space may be indicated. The risks of cardiac and respiratory failure or arrest are high with severe disease. All fluids, electrolytes, and medications are initially given parenterally. In prolonged states of coma, parenteral alimentation is indicated. SIADH is common in acute CNS disorders; monitoring of serum sodium concentrations is required for early detection (see Chapter 559). Normal blood levels of glucose, magnesium, and calcium must be maintained to minimize the likelihood of convulsions. If cerebral edema or seizures become evident, vigorous treatment should be instituted.

PROGNOSIS

Supportive and rehabilitative efforts are very important after patients recover from the acute phase of illness. Motor incoordination, convulsive disorders, total or partial deafness, and behavioral disturbances may follow viral CNS infections. Visual disturbances from chorioretinopathy and perceptual amblyopia may also occur. Special facilities and, at times, institutional placement may become necessary. Some sequelae of infection may be very subtle. Therefore, neurodevelopmental and audiologic evaluations should be part of the routine follow-up of children who have recovered from viral meningoencephalitis.

Most children completely recover from viral infections of the CNS, although the prognosis depends on the severity of the clinical illness, the specific causative organism, and the age of the child. If the clinical illness is severe and substantial parenchymal involvement is evident, the prognosis is poor, with potential deficits being intellectual, motor, psychiatric, epileptic, visual, or auditory in nature. Severe sequelae should also be anticipated in those with infection caused by HSV. Although some literature suggests that infants who contract viral meningoencephalitis have a poorer long-term outcome than older children, most other data refute this observation. Approximately 10% of children younger than 2 yr of age with enteroviral CNS infections suffer an acute complication such as seizures, increased ICP, or coma. Almost all have favorable long-term neurologic outcomes.

PREVENTION

Widespread use of effective viral vaccines for polio, measles, mumps, rubella, and varicella has almost eliminated CNS complications from these diseases in the United States. The availability of domestic animal vaccine programs against rabies has reduced the frequency of rabies encephalitis. Control of encephalitis caused by arboviruses has been less successful because specific vaccines for the arboviral diseases that occur in North America are not available. Control of insect vectors by suitable spraying methods and eradication of insect breeding sites, however, reduces the incidence of these infections. Furthermore, minimizing mosquito bites through the application of N,N-diethyl-3-methylbenzamide (DEET)-containing insect repellents on exposed skin and wearing long-sleeved shirts, long pants, and socks when outdoors, especially at dawn and dusk, reduces the risk of arboviral infection.

603.3 Eosinophilic Meningitis

Charles G. Prober and Nivedita S. Srinivas

Eosinophilic meningitis is defined as 10 or more eosinophils/mm$^3$ of CSF. The most common cause worldwide of eosinophilic pleocytosis is CNS infection with helminthic parasites. In countries such as the United States, where helminthic infestation is uncommon, however, the differential diagnosis of CSF eosinophilic pleocytosis is broad.

ETIOLOGY

Although any tissue-migrating helminth may cause eosinophilic meningitis, the most common cause is human infection with the rat lungworm, Angiostrongylus cantonensis (see Chapter 297). Other parasites that can cause eosinophilic meningitis include Gnathostoma spinigerum (dog and cat roundworm) (see Chapter 297), Baylisascaris procyonis (raccoon roundworm), Ascariis lumbricoides (human roundworm), Trichinella spiralis, Toxocara canis, T. gondii, Paragonimus westermani, Echinococcus granulosus, Schistosoma japonicum, Oncho cercia volvulus, and Taenia solium. Eosinophilic meningitis may also occur as an unusual manifestation of more common viral, bacterial, or fungal infections of the CNS. Noninfectious causes of eosinophilic meningitis include multiple sclerosis, malignancy, hypereosinophilic syndrome, or a reaction to medications or a ventriculoperitoneal shunt.

EPIDEMIOLOGY

A. cantonensis is found in Southeast Asia, the South Pacific, Japan, Taiwan, Egypt, Ivory Coast, and Cuba. Infection is acquired by eating raw or undercooked freshwater snails, slugs, prawns, or crabs containing infectious 3rd-stage larvae. Gnathostoma infections are found in Japan, China, India, Bangladesh, and Southeast Asia. Gnathostomiasis is acquired by eating undercooked or raw fish, frog, bird, or snake meat.

CLINICAL MANIFESTATIONS

When eosinophilic meningitis results from helminthic infestation, patients become ill 1-3 wk after exposure. This reflects the transit time for parasites to migrate from the gastrointestinal tract to the CNS. Common concomitant findings include fever, peripheral eosinophilia, vomiting, abdominal pain, creeping skin eruptions, or pleurisy. Neurologic symptoms may include headache, meningismus, ataxia, cranial nerve palsies, and paresthesias. Paraparesis or incontinence can result from radiculitis or myelitis.

DIAGNOSIS

The presumptive diagnosis of helminth-induced eosinophilic meningitis is most often based on travel and exposure history in the presence of typical clinical and laboratory findings. Direct visualization of helminths in CSF is affected by the relatively low organism burden, resulting in limited diagnostic sensitivity. Serologic assays for helminthic infections are also of limited utility because they are not readily available commercially and there is substantial cross-reactivity between different helminth species.

TREATMENT

Treatment is supportive, because infection is self-limited and anthelminthic drugs do not appear to influence the outcome of infection. Analgesics should be given for headache and radiculitis, and CSF removal or shunting should be performed to relieve hydrocephalus, if present. Steroids may decrease the duration of headaches in adults with eosinophilic meningitis.

PROGNOSIS

The prognosis is good; 70% of patients improve sufficiently to leave the hospital in 1-2 wk. Mortality associated with eosinophilic meningitis is <1%.

Chapter 603  Central Nervous System Infections 2948.e1

Bibliography

Bibliography

Brain abscesses can occur in children of any age but are most common in children between 4 and 8 yr old and in neonates. The causes of brain abscess include embolization as a result of congenital heart disease with right-to-left shunts (especially tetralogy of Fallot), endocarditis, meningitis, chronic otitis media and mastoiditis, sinusitis, soft-tissue infection of the face or scalp, orbital cellulitis, dental infections, severe complicated pneumonia, penetrating head injuries, immunodeficiency states, and infection of ventriculoperitoneal shunts.

**PATHOLOGY**

Cerebral abscesses are evenly distributed between the 2 hemispheres, and 80% of cases are divided equally between the frontal, parietal, and temporal lobes. Brain abscesses in the occipital lobe, cerebellum, and brainstem account for approximately 20% of the cases. Most brain abscesses are single, but 30% are multiple and may involve more than 1 lobe. The pathogenesis is undetermined in 10-15% of cases. An abscess in the frontal lobe is often caused by extension from sinusitis or orbital cellulitis, whereas abscesses located in the temporal lobe or cerebellum are frequently associated with chronic otitis media and mastoiditis. Abscesses resulting from penetrating injuries tend to be singular and caused by *Staphylococcus aureus*, whereas those resulting from septic emboli, congenital heart disease, or meningitis often have several causal organisms.

**ETIOLOGY**

The predominant organisms causing brain abscesses in children are aerobic and anaerobic streptococci (60-70% of the cases) with *Streptococcus milleri* gp (*Streptococcus anginosus*, *Streptococcus constellatus*, and *Streptococcus intermedius*) being increasingly isolated from surgically drained brain abscesses. Other important streptococci include group A and B streptococci, *Streptococcus pneumoniae*, and *Enterococcus faecalis*. Other bacteria isolated from brain abscesses include anaerobic organisms (Gram-positive cocci, *Bacteroides* spp., *Fusobacterium* spp., *Prevotella* spp., *Actinomyces* spp.) and Gram-negative aerobic bacilli (*Haemophilus aphrophilus*, *Haemophilus parainfluenzae*, *Haemophilus influenzae*, *Enterobacter*, *Escherichia coli*, *Proteus* spp.). *Citrobacter* is most common in neonates. One organism is cultured in 70% of abscesses, 2 in 20%, and 3 or more in 10% of cases. Abscesses associated with mucosal infections (sinusitis) frequently have anaerobic bacteria. Fungi (*Aspergillus*, *Candida*), *Nocardia*, *Mycobacterium*, and *Listeria* spp. are more common in children with impaired host defenses.

**CLINICAL MANIFESTATIONS**

The early stages of cerebritis and abscess formation are associated with nonspecific symptoms, including low-grade fever, headache, and lethargy. The significance of these symptoms is generally not recognized, and an oral antibiotic is often prescribed with resultant transient relief. As the inflammatory process proceeds, vomiting, severe headache, seizures, papilledema, focal neurologic signs (hemiparesis), and coma may develop. A cerebellar abscess is characterized by nystagmus, ipsilateral ataxia and dysmetria, vomiting, and headache. If the abscess ruptures into the ventricular cavity, overwhelming shock and death usually ensue.

**DIAGNOSIS**

The peripheral white blood cell count can be normal or elevated, and the blood culture is positive in 10% of cases. Examination of the cerebrospinal fluid shows variable results; the white blood cells and protein may be minimally elevated or normal, and the glucose level may be low. Cerebrospinal fluid cultures are rarely positive; culture of pus from the neurosurgical drainage is the key to establishing a bacteriologic diagnosis. However, the culture can be sterile in a substantial number of cases and 16S bacterial ribosomal RNA polymerase chain reaction amplification and sequencing may be used to identify unculturable bacteria in brain abscesses. Because examination of the cerebrospinal fluid is seldom useful and a lumbar puncture may cause herniation of the cerebellar tonsils, the procedure should not be undertaken in a child suspected of having a brain abscess. The electroencephalogram shows corresponding focal slowing, and the radionuclide brain scan indicates an area of enhancement caused by disruption of the blood–brain barrier in more than 80% of cases. CT with contrast and MRI are the most reliable methods of demonstrating cerebritis and abscess formation (Fig. 604-1). MRI is the diagnostic test of choice. The CT findings of cerebritis are characterized by a parenchymal low-density lesion, and MRI T2-weighted images indicate increased signal intensity. An abscess cavity shows a ring-enhancing lesion by contrast CT, and the MRI also demonstrates an abscess capsule with gadolinium administration.

**TREATMENT**

The initial management of a brain abscess includes prompt diagnosis and institution of an antibiotic regimen that is based on the probable pathogenesis and the most likely organism. When the cause is unknown, the combination of vancomycin, a third-generation cephalosporin, and metronidazole is commonly used. The same regimen is initiated when otitis media, sinusitis, or mastoiditis is the likely cause. If there is a history of penetrating head injury, head trauma, or neurosurgery; vancomycin plus a third-generation cephalosporin is appropriate. When cyanotic congenital heart disease is the predisposing factor, ampicillin-sulbactam alone or a third-generation cephalosporin plus metronidazole may be used. Meropenem has good activity against Gram-negative bacilli, anaerobes, *staphylococci*, and *streptococci*,
including most antibiotic-resistant pneumococci, and may be used alone to replace the combination of metronidazole and a β-lactam in the previous regimens. Notably, meropenem does not provide activity against methicillin-resistant S. aureus and may have decreased activity against penicillin-resistant strains of S. pneumoniae, indicating that vancomycin should remain a part of the initial regimen when these organisms are suspected. Abscesses secondary to an infected ventriculoperitoneal shunt may be initially treated with vancomycin and cefazidime. When Citrobacter meningitis (often in neonates) leads to abscess formation, a third-generation cephalosporin is used, typically in combination with an aminoglycoside. Listeria monocytogenes may cause a brain abscess in the neonate and if suspected, ampicillin should be added to the cephalosporin. In immunocompromised patients, broad-spectrum antibiotic coverage is used, and amphotericin B therapy should be considered.

A brain abscess can be treated with antibiotics without surgery if the abscess is <2 cm in diameter, the illness is of short duration (<2 wk), there are no signs of increased intracranial pressure, and the child is neurologically intact. If the decision is made to treat with antibiotics alone, the child should have follow-up neuroimaging studies to ensure the abscess is decreasing in size. An encapsulated abscess, particularly if the lesion is causing a mass effect or increased intracranial pressure, should be treated with a combination of antibiotics and aspiration. Surgical excision of an abscess is rarely required, because the procedure may be associated with greater morbidity compared with aspiration of a cavity. Surgery is indicated when the abscess is ≥2.5 cm in diameter, gas is present in the abscess, the lesion is multiloculated, the lesion is located in the posterior fossa, or a fungus is identified. Associated infectious processes, such as mastoiditis, sinusitis, or a periorbital abscess, may require surgical drainage. The duration of antibiotic therapy depends on the organism and response to treatment but is usually 4-6 wk.

**PROGNOSIS**

Mortality rates prior to 1980s ranged from 11-53%. More recent mortality rates accompanying wider use of CT and MRI, improved microbiologic techniques and prompt antibiotic and surgical management, range from 5-10%. Factors associated with high mortality rate at the time of admission include age younger than 1 yr, multiple abscesses and coma. Long-term sequelae occur in about one-third of the survivors and include hemiparesis, seizures, hydrocephalus, cranial nerve abnormalities, and behavior and learning problems.

*Bibliography is available at Expert Consult.*
Bibliography

Idiopathic intracranial hypertension, also known as pseudotumor cerebri, is a clinical syndrome that mimics brain tumors and is characterized by increased intracranial pressure ≥280 mm Hg in sedated or obese children; ≥250 mm Hg in nonobese, nonsedated children with a normal cerebrospinal fluid (CSF) cell count and protein content and normal to slightly decreased ventricular size, and normal ventricular anatomy and position documented by MRI. Papilledema is universally present in children old enough to have a closed fontanel (Fig. 605-1).

ETIOLOGY

Table 605-1 lists the many causes of pseudotumor cerebri. There are many explanations for the development of pseudotumor cerebri, including alterations in CSF absorption and production, subtle cerebral edema, abnormalities in vasomotor control and cerebral blood flow, and venous obstruction. The causes of pseudotumor are numerous and include metabolic disorders (galactosemia, hypoparathyroidism, pseudohypoparathyroidism, hypophosphatasia, prolonged corticosteroid therapy or rapid corticosteroid withdrawal, possibly growth hormone treatment, refeeding of a significantly malnourished child, hypervitaminosis A, severe vitamin A deficiency, Addison disease, obesity, menarche, oral contraceptives, and pregnancy), infections (roseola infantum, sinusitis, chronic otitis media and mastoiditis, Guillain-Barré syndrome), drugs (nalidixic acid, doxycycline, minocycline, tetracycline, nitrofurantoin, isotretinoin used for acne therapy especially when combined with tetracycline), hematologic disorders (polycythemia, hemolytic and iron-deficiency anemias [see Fig. 605-1],

Figure 605-1 Optic nerve photos of the right and left eyes, respectively, demonstrating grade 5 optic nerve head edema with characteristics, including (A) total obscurcation of the optic cup; (B) total obscurcation of a segment of a major blood vessel; (C) total obscurcation of disc margin; and (D) macular star. Wiskott-Aldrich syndrome, obstruction of intracranial drainage by venous thrombosis (lateral sinus or posterior sagittal sinus thrombosis), head injury, and obstruction of the superior vena cava. When a cause is not identified, the condition is classified as idiopathic intracranial hypertension.

**CLINICAL MANIFESTATIONS**

The most frequent symptom is chronic (weeks to months), progressive, frontal headache that may worsen with postural changes or a Valsalva maneuver, and although vomiting also occurs, the vomiting is rarely as persistent and insidious as that associated with a posterior fossa tumor. Transient visual obscuration lasting seconds and diplopia (secondary to dysfunction of the abducens nerve) may also occur as may pulsatile tinnitus. Most patients are alert and lack constitutional symptoms. Examination of the infant with pseudotumor cerebri characteristically reveals a bulging fontanel and a “cracked pot sound” or Macwen sign (percussion of the skull produces a resonant sound) resulting from separation of the cranial sutures. Papilledema with an enlarged blind spot is the most consistent sign in a child beyond infancy. Papilledema may be absent or mild in infants with pseudotumor cerebri because high CSF pressure may be transmitted to the soft fontanels earlier than the optic nerves. Early optic nerve edema may be noted with orbit ultrasonography. Inferior nasal or peripheral visual field defects may be detected on formal tangent screen testing. The presence of focal neurologic signs should prompt an investigation to uncover a process other than pseudotumor cerebri. Any patient suspected of pseudotumor cerebri should undergo an MRI. MR angiography/MR venography should be considered in patients suspected of having dural sinus thrombosis.

**TREATMENT**

The key objective in management is recognition and treatment of the underlying cause. There are no randomized clinical trials to guide the treatment of pseudotumor cerebri. Pseudotumor cerebri can be a self-limited condition, but optic atrophy and blindness are the most significant complications of untreated pseudotumor cerebri (Fig. 605-2). The obese patient should be treated with a weight-loss regimen, and if a drug is thought to be responsible, it should be discontinued. For most patients old enough to participate in such testing, serial monitoring of visual function is required. Serial determination of visual acuity, color vision, and visual fields is critical in this disease. Serial optic nerve examination is essential as well. Optical coherence tomography is useful to serially follow changes in papilledema. Serial visual-evoked potentials are useful if the visual acuity cannot be reliably documented. The initial lumbar tap that follows a CT or MRI scan is diagnostic and useful to serially follow changes in papilledema. Serial visual-evoked potentials are useful if the visual acuity cannot be reliably documented. The initial lumbar tap that follows a CT or MRI scan is diagnostic and may be therapeutic. The spinal needle produces a small rent in the dura that allows CSF to escape the subarachnoid space, thus reducing the intracranial pressure. Several additional lumbar taps and the removal

Figure 605-2 Bilateral optic atrophy is evident upon resolution of the papilledema, 1 mo after bilateral optic nerve sheath fenestrations. (From Vickers AL, El-Dairi MA: Subacute vision loss in young, obese female. J Pediatr 163:1518–1519, 2013, Fig. 2.)
of sufficient CSF to reduce the opening pressure by 50% occasionally lead to resolution of the process. Acetazolamide, 10-30 mg/kg/24 hr, is an effective regimen. Corticosteroids are not routinely administered, although they may be used in a patient with severe intracranial pressure elevation who is at risk of losing visual function and is awaiting a surgical decompression. Sinus thrombosis is typically addressed by anticoagulation therapy. Rarely, a ventriculoperitoneal shunt or subtemporal decompression is necessary, if the aforementioned approaches are unsuccessful and optic nerve atrophy supervenes. Some centers perform optic nerve sheath fenestration to prevent visual loss. Any patient whose intracranial pressure proves to be refractory to treatment warrants consideration for repeat neuroradiologic studies. A slow-growing tumor or obstruction of a venous sinus may become evident by the time of reinvestigation.

Chapter 605  Idiopathic Intracranial Hypertension/Pseudotumor Cerebri

Bibliography
Beyond infancy the spinal cord in humans ends in the conus medullaris at about the level of L1. The position of the conus below L2 is consistent with a congenital tethered spinal cord. For normal humans as the spine flexes and extends, the spinal cord is free to move up and down within the spinal canal. If the spinal cord is fixed at any point, this movement is restricted and the spinal cord and nerve roots become stretched. This fixing of the spinal cord, regardless of the underlying cause of the fixation, is called a tethered cord. When severe pain or neurologic deterioration occurs in response to the fixation, it is called the tethered cord syndrome.

In its simplest form the tethered cord syndrome results from a thickened filum terminale, which normally extends as a thin, very mobile structure from the tip of the conus to the sacrococcygeal region where it attaches. When this structure is thickened and shortened, the conus is found to end at levels below L2. This stretching between 2 points is likely to cause symptoms later in life. Fatty infiltration is often seen in the thickened filum (Fig. 606-1).

Any condition that fixes the spinal cord can be the cause of the tethered cord syndrome. Conditions that are well established to cause symptomatic tethering include various forms of occult dysraphism such as lipomyelomeningocele, myelocystocele, and diastematomyelia. These conditions are associated with cutaneous manifestations such as midline lipomas often with asymmetry of the gluteal fold (Fig. 606-2), and hairy patches called hypertrichosis (Fig. 606-3). Probably the most common type of symptomatic tethered cord involves patients who had previously undergone closure of an open myelomeningocele and later become symptomatic with pain or neurologic deterioration. Tethered cord syndrome can also be associated with attachment of the spinal cord in patients who undergo surgical procedures that disrupt the pial surface of the spinal cord.

It is possible that a patient can be suffering from a tethered cord with the conus medullaris in a completely normal position. Although this concept remains controversial, recent reports suggest that half of children with new onset of incontinence found to be neurologic in nature by urodynamic measurements can be successfully treated by sectioning of the filum terminale in the context of normal radiology. This concept will require a randomized controlled trial to evaluate the efficacy of this approach.

**CLINICAL MANIFESTATIONS**

Patients at risk for the subsequent development of the tethered cord syndrome can often be identified at birth by the presence of an open myelomeningocele or by cutaneous manifestations of dysraphism. It is important to examine the back of the newborn for cutaneous midline lesions (lipoma, dermal sinus, tail, or hairy patch) that may signal an
DIASTEMATOMYELIA: SPLIT-CORD MALFORMATION

Diastematomyelia is a relatively rare form of occult dysraphism in which the spinal cord is divided into 2 halves. In type 1 split-cord malformation, there are 2 spinal cords, each in its own dural tube and separated by a spicule of bone and cartilage (Fig. 606-5A). In a type 2 split-cord malformation, the 2 spinal cords are enclosed in a single dural sac with a fibrous septum between the 2 spinal segments (Fig. 606-5B). In both cases the anatomy of the outer half of the spinal cord is essentially normal while the medial half is extremely underdeveloped. Undeveloped nerve roots and denticate ligaments terminate medially into the membranous dural tube in type 1 cases and terminate in the membranous septum in type 2 cases. Both types have an associated Brachynotia, the most common cutaneous manifestations, are present in approximately 60% of the cases. Dermal sinuses are usually located above the gluteal fold. Cutaneous abnormalities are not found in patients with an isolated thickened filum terminale. Patients who become symptomatic later in life often exhibit an asymmetry of the feet (i.e., 1 is smaller than the other). The smaller foot will show a high arch and clawing of the toes (Fig. 606-4). Characteristically, there is no ankle jerk on the involved side and the calf is atrophied. This condition is termed the neuroorthopedic syndrome.

Three clinical syndromes can occur at the time of deterioration. The most likely clinical presentation is increasing urinary urgency and, finally, incontinence. Deterioration of motor and sensory function in the lower extremities is a compelling reason for intervention. Finally, severe generalized back pain, often radiating into the lower extremities, can occur, particularly in older adolescents and adults.

DIAGNOSTIC EVALUATION

When patients present with symptoms related to the tethered cord syndrome, a thorough motor and sensory examination of the patient must be documented. Assessment of bladder function with an ultrasound of the bladder and urodynamic studies is useful in analyzing bladder innervation. MRI is the diagnostic study of choice to reflect the anatomy of the tethering lesion and to provide information about the risks of surgical intervention.

TREATMENT

There are no nonsurgical options for the management of tethered cord syndrome. Because the presence of tethering is most likely to be at least suspected in the newborn, prophylactic surgery to prevent late deterioration has been advocated by some neurosurgeons. This strategy remains controversial and depends to some extent on a careful assessment of the risks compared to the benefits. If surgical intervention is chosen, microsurgical dissection with release of the spinal cord attachment to the overlying dura is the goal of treatment.

OUTCOME

The outcome of releasing a thickened filum terminale or detethering of patients with diastematomyelia is routinely good, and the chance of recurrent symptoms is very low. Patients with symptomatic tethered cord who undergo repair of a myelomeningocele or a lipomyelomeningocele have a significant possibility of recurrent tethering and recurrent symptoms.

606.2 Diastematomyelia

Harold L. Rekate

MRI, the study of choice, shows the 2 spinal cords. The frequent association of bony abnormalities in this condition may require further evaluation with radiography or computed tomography.

TREATMENT

The treatment of split-cord malformations is surgical. This abnormality is a form of tethered cord syndrome, and its treatment is to release the spinal cord to move freely with movement of the spine. In type 1 split-cord malformations, the 2 half cords are in separate dural sacs with medial attachment to the dura and bony septum. In this case the dura needs to be opened, the bony septum removed, the medial attachments to the dura lysed, and a single dural tube created. For type 2 lesions,
Bibliography
the membranous septum should be lysed. An attachment of this membrane to the anterior dura should be explored and lysed as well. Retethering of this type is rare as there is no reason to disrupt the pial layer of the spinal cord.

Bibliography is available at Expert Consult.

606.3 Syringomyelia
Harold L. Rekate

Syringomyelia is a cystic distention of the spinal cord caused by obstruction of the flow of spinal fluid from within the spinal cord to its point of absorption. There are 3 recognized forms of syringomyelia depending on the underlying cause. Communicating syringomyelia implies that cerebrospinal fluid (CSF) from within the ventricles communicates with the fluid within the spinal cord and is assumed to be the source of the CSF that distends the spinal cord. Noncommunicating syringomyelia implies that ventricular CSF does not communicate with the fluid within the spinal cord. It primarily occurs in the context of intramedullary tumors and obstructive lesions. In the final form of syringomyelia, that is, posttraumatic syringomyelia, spinal cord injury results in damage and subsequent softening of the spinal cord. This softening, combined with the scarring of the surrounding spinal cord tissue, results in progressive distention of the cyst. Syringomyelia has been associated with Chiari anomalies and in patients with Ehlers-Danlos syndrome; most are isolated findings unassociated with syndromes.

CLINICAL MANIFESTATIONS

Signs and symptoms of syringomyelia develop insidiously over years or decades. The classic presentation is the central cord syndrome. In this situation the patient develops numbness beginning in the shoulder in a cape-like distribution followed by the development of atrophy and weakness in the upper extremities. Trophic ulcers of the hands are characteristic of advanced cases. The central cord syndrome results from damage to the central spinal cord and the orientation of spinal tracts from proximal to distal leading to selective involvement of the upper rather than the lower extremities.

Other forms of presentation include scoliosis that may be rapidly progressive and often can be presumed from the absence of superficial abdominal reflexes. Urgency and bladder dysfunction as well as lower extremity spasticity also may be part of the presentation.

In patients with syringomyelia related to spinal cord injury, the presentation is usually severe pain in the area of the spinal cord distention above the level of the initial injury. There is also an ascending level of motor and sensory dysfunction.

DIAGNOSTIC EVALUATION

MRI is the radiologic study of choice (Figs. 606-6 and 606-7). The study should include the entire spine and should include gadolinium-enhanced sequences. Specific attention should be paid to the craniocervical junction because of the frequent association of syringomyelia with Chiari I and II malformations. Obstruction to the flow of CSF from the fourth ventricle can cause syringomyelia; therefore, most patients also should undergo imaging of the brain.
**Bibliography**

TREATMENT
The treatment of syringomyelia should be tailored to the underlying cause. If that cause can be removed or ameliorated, the syrinx should improve. Traumatic syringes result from hematomyelia in the substance of the spinal cord coupled with severe arachnoidal scarring around the circumference of the spinal cord. When progressive this form of syringomyelia is treated by exploration and lysis of the adhesions that fix the spinal cord to the overlying dura. In cases of complete spinal cord injury, as is usually found in the thoracic spinal cord, the most effective treatment is the transection of the spinal cord, which would both drain the syrinx and detether the spinal cord. Doing so drains the fluid from the spinal cord. In cases of incomplete spinal cord injury, functioning neurologic elements must be protected. Microscopic lysis of the scar surrounding the spinal cord at the point of injury allows the spinal cord to collapse and prevents it from being distorted by a hydrostatic column.

Communicating syringomyelia is most frequently seen in the context of abnormalities at the craniovertebral junction caused by inflammatory conditions such as chronic meningitis as seen in tuberculosis or meningeval carcinomatosis. There is frequently a causative association with hindbrain herniation as in Chiari malformations (see Fig. 606-6). In such cases decompression of the craniovertebral junction is usually effective in the management of the syringomyelia. In the context of the Chiari II malformation associated with spina bifida, syringomyelia usually results from an insidious failure of the shunt used to treat the hydrocephalus. This distention of the spinal cord results in a rapid development of scoliosis and occasionally spasticity in the lower extremities. Repair of the shunt is effective treatment.

Noncommunicating syringomyelia results from blocking the flow of spinal cord extracellular fluid or CSF within the central canal by an intramedullary spinal cord tumor or severe external compression of the spinal cord. In such cases, management should be directed to tumor resection or to decompression of constricting elements.

Drainage procedures can result in symptomatic and radiographic improvement. Syrinx-to-subarachnoid shunting with a small piece of shunt tubing is 1 form of treatment. Syrinx-to-pleural or syrinx-to-peritoneal shunting is more likely to result in improvement in the radiographic appearance of the syrinx. In patients with syringomyelia that extends to the conus medullaris, remnants of the central canal can be found in the filum terminale. Lysis of this structure near the conus can provide effective drainage.

Some children who show no testable neurologic findings are being referred to pediatric neurosurgeons with the diagnosis of syringomyelia. Many of these children were scanned because of back pain or as part of a screening for scoliosis. They are found on MRI to have a persistent central canal and the diagnosis of syringomyelia is made. Some have been scanned sequentially for follow up and banned from athletic activities. These syrinxes are 1-3 mm in diameter and extend over 2 segments (see Fig. 606-7). There is no distortion of the spinal cord in the region and no change in signal of the surrounding spinal cord. These syrinxes have been called “idiopathic” syrinxes. Follow-up of significant numbers of such children has shown them to be benign in nature and probably represent a normal variant. There does not seem to be a need for routine follow-up imaging without new symptoms. They need no treatment and do not require limitations of activity.

Bibliography is available at Expert Consult.

606.4 Spinal Cord Tumors
Harold L. Rekate

Tumors of the spine and spinal cord are rare in children. Different types of tumors have different relationships with the spinal cord, meninges, and bony elements of the spine (Fig. 606-8). Intramedullary spinal cord tumors arise within the substance of the spinal cord itself (Fig. 606-9). They represent between 5% and 15% of primary central nervous system tumors. This percentage may well reflect the total volume of spinal cord as opposed to brain. Approximately 10% of intramedullary spinal cord tumors are malignant astrocytic tumors, but most are World Health Organization grade I or II tumors of glial or ependymal origin. In children, low-grade astrocytomas and gangliogliomas represent the most common tumor types with ependymomas being less common than in adults. Ependymomas in children are frequently associated with neurofibromatosis (NF-2).

Except in the context of NF-1 and NF-2, intradural extramedullary tumors are extremely rare in children. Most are nerve sheath tumors,
Bibliography
the exiting spinal nerve. They are very slow-growing tumors and interfere with normal CSF flow dynamics. Tumors are associated with markedly elevated CSF protein levels that presumably inter
spasticity, and ataxia, with contralateral loss of pain and temperature retention, and a patulous anus. Some extramedullary tumors produce
fined space. Such children present with a flaccid paraplegia, urinary acute block of the CSF pathways owing to rapid growth within a con

DRUGS AND DRUG TREATMENT
The standard drug treatment for malignant brain tumors involves systemic chemotherapy and radiotherapy. Systemic chemotherapy is often

CLINICAL MANIFESTATIONS
With the exception of the uncommon malignant glial tumors of the spinal cord, which tend to present precipitously, intramedullary spinal cord tumors present in a very insidious manner. Back pain related to the level of the tumor is a common presenting complaint. It is likely that this pain will awaken the child from sleep and improve as the day progresses. Before the use of MRI became routine, the time from the first onset of symptoms to diagnosis of the tumor could be as long as 9 yr. Weakness, gait disturbance, and sensory deficits are usually minor and are often found when formal neurologic examinations are performed. Scoliosis, urinary urgency, and incontinence may be the presenting complaints associated with intramedullary spinal cord tumors.

Extradural spinal tumors characteristically begin in the bones of the spine. Primary tumors in this location include aneurysmal bone cysts, Langerhans cell histiocytosis (formerly called eosinophilic granuloma), and giant cell tumors. In infants, the extradural space is often the site of neuroblastomas or ganglioneuroblastomas, which tend to be present in the epidural space and in the paraspinous tissue through the inter-vertebral foramen. In older patients, the bones of the spine may be the site of multiple myeloma and metastases from common malignant tumors.

DIAGNOSTIC EVALUATION
MRI with and without gadolinium enhancement of the spinal cord is the diagnostic study of choice and is essential in the diagnosis of spinal cord tumors, especially intramedullary spinal cord tumors. Most astrocytic tumors of the spinal cord and most ependymomas show diffuse enhancement and will distend the spinal cord focally. These tumors may involve the entire length of the spinal cord (holocord astrocytomas). MRI also shows the relationship between the normal spinal cord and tumor embedded within spinal cord tissue. These tumors are frequently associated with a syrinx, which is usually distal to the tumor. Nerve sheath tumors characteristically enhance and are focal. They may exit through the neural foramen and distend the canal as can be seen on MRI. They also may be visualized on plain radiographs of the affected area of the spine.

Plain radiographs of the spine are helpful in defining the relationship of extradural tumors to the bony spine and in documenting evidence of instability in the case of pathologic compression fractures. When a pathologic fracture occurs, CT is essential to determine the effect of the tumor on the bone. Because many of these tumors occur as meta-
static lesions, a general staging of the extent of disease is essential. In the case of Langerhans cell histiocytosis, a thorough bone survey should be conducted to look for other lesions. Radionuclide bone scanning is also useful in determining the extent of the disease.

TREATMENT
The primary treatment of both intramedullary and extramedullary intradural tumors is surgical removal. For both low-grade astrocytomas and ependymomas, microsurgical removal with the intent of total removal is the treatment of choice. This goal should be attainable in all patients with ependymomas and in most patients with low-grade astrocytomas and gangliogliomas. Adjunctive treatment of these tumors is unwarranted in patients treated with adequate surgical resection. Likewise, schwannomas should be resectable. Occasionally, however, the nerve root must be resected. Doing so may be of no consequence in the thoracic spinal cord, but an attempt to remove the tumor while salvaging the motor root in the cervical and lumbosacral region is critical to preserve movement. Malignant astrocytic tumors cannot be resected without major morbidity and, in any case, carry an extremely poor prognosis. In the case of grades III and IV astrocytomas of the spinal cord, decompression and biopsy followed by radiation therapy and possibly chemotherapy are utilized.

The diagnosis and treatment of extramedullary spinal cord tumors must be individualized. Patients with distortion of the vertebral body or with unstable pathologic fractures benefit from extensive resection of the involved vertebral bodies and will likely need fusion. For extra-
medullary tumors with soft-tissue components such as neuroblastomas, treatment is determined by the nature of the tumor and degree of spinal cord compression, and directed following needle biopsy of the lesion. In the absence of significant neurologic compression, surgical intervention is rarely indicated.

OUTCOME
The prognosis for patients with benign intramedullary spinal cord tumors depends, to some extent, on the patient’s condition at the time of surgical intervention. It is very unlikely that nonambulatory patients will improve after surgery. If, however, patients are ambulatory at the time of surgery, they may experience increased weakness after surgery.
They are likely to recover at least their preoperative level of function. Malignant spinal cord tumors are usually lethal with death resulting from diffuse metastases via the CSF pathways. Successful resection of nerve sheath tumors should be curative. In the context of neurofibromatosis, however, many more tumors can be found at other levels or can be expected to develop later in life. Surgical intervention in the context of neurofibromatoses should be performed only on clearly symptomatic lesions.

The outcome of treatment of extramedullary tumors depends on the cell type and, in most cases, on the efficacy of nonsurgical, adjunctive therapies. For aneurysmal bone cysts and giant cell tumors, resection of the tumor and fusion of the spine are the treatments of choice.

The significant majority of spinal cord tumors in children are benign (World Health Organization grades 2 and 3). The intramedullary low-grade glial tumors for the most part act the same as the same histology in the brain. The evidence would point to the fact that intramedullary ependymomas act in a more benign fashion than they do in the fourth ventricle. Gross total removal without adjuvant treatment is the preferred method of treatment and carries not only much longer progression free survival but improved quality of life as well.

Bibliography is available at Expert Consult.

606.5 Spinal Cord Injuries in Children
Harold L. Rekate

Spine and spinal cord injuries are very rare in children, particularly in young children. The spine of a small child is very mobile, and fractures of the spine are exceedingly rare. This increased mobility is not always a positive feature. Transfer of energy leading to spinal distortion can maintain the structural integrity of the spine but lead to significant injuries of the spinal cord. Spinal cord injury without radiographic bone (vertebral) abnormalities, called SCIWORA, is more common in children than adults. There seem to be 2 distinct forms. The infantile form involves severe injury of the cervical or thoracic spine. These patients have a poor likelihood of complete recovery. In older children and adolescents, SCIWORA is more likely to cause a less-severe injury and the likelihood of complete recovery over time is high. The adolescent form is assumed to be a spinal cord concussion or mild contusion as opposed to the severe spinal cord injury related to the mobility of the spine in small children.

Although the mechanisms of spinal cord injury in children include birth trauma, falls, and child abuse, the major cause of morbidity and mortality remains motor vehicle injuries. Although the mechanisms of injury and diagnosis are distinct in very small children, adolescents incur spinal cord injuries with epidemiology similar to that of adults, including significant male predominance and a high likelihood of fracture dislocations of the lower cervical spine or thoracolumbar region. In infants and children younger than age 5 yr, fractures and mechanical disruption of spinal elements are limited to the upper cervical spine between the occiput and C3.

CLINICAL MANIFESTATIONS
One in 3 patients with significant trauma to the spine and spinal cord will have a concomitant severe head injury, which makes early diagnosis challenging. For these patients clinical evaluation may be difficult. They need to be maintained in a protective environment such as a collar until the appropriate radiographs can be obtained. A careful neurologic examination is necessary for infants with suspected spinal cord injuries. Complete spinal cord injury will lead to spinal shock with early areflexia. Severe cervical spinal cord injuries will usually lead to paradoxical respiration in patients who are breathing spontaneously. Paradoxical respiration occurs when the diaphragm functions because the phrenic nerves from C3, C4, and C5 are functioning normally but the intercostal musculature innervated by the thoracic spinal cord is paralyzed. In this situation, inspiration fails to expand of the chest wall but distends the abdomen.

The mildest injury to the spinal cord is transient quadriparesis evident for seconds or minutes with complete recovery in 24 hr. This injury follows a concussion of the cord.

A transverse injury in the high cervical cord level (C1-C2) causes respiratory arrest and death in the absence of ventilatory support. Fracture dislocations at the C5-C6 level resulting in spinal cord injuries are characterized by flaccid quadriparesis, loss of sphincter function, and a sensory level corresponding to the upper sternum. Fractures or dislocations in the low thoracic (T12-L1) region may produce the conus medullaris syndrome, which includes a loss of urinary and rectal sphincter control, flaccid weakness, and sensory disturbances of the legs. A central cord lesion may result from contusion and hemorrhage and typically involves the upper extremities to a greater degree than the legs. There are lower motor neuron signs in the upper extremities and upper motor neuron signs in the legs, bladder dysfunction, and loss of sensation caudal to the lesion. There may be considerable recovery, particularly in the lower extremities.

Thoracolumbar injuries are usually fracture–dislocations such as occur in severe motor vehicle accidents when children are wearing lap belts but not shoulder harnesses. These injuries lead to a conus medullaris syndrome. These patients exhibit a loss of bowel and bladder function and lower motor neuron injuries involving the innervation of the lower extremities.

CLEARING THE CERVICAL SPINE IN CHILDREN
The management of children following major trauma is challenging. Clearing the cervical spine in children carries some of the same issues as it does in comatose adults in that with small children you cannot count on their cooperation with positioning for radiographs and complaints of pain are difficult to assess. There has been an increasing emphasis on the use of MRI for the evaluation of potential cervical spine instability but in small children this study requires sedation and, in most centers, the presence of an anesthesiologist. Despite the radiation dose, it is clear that the CT scan is the most important study with 100% sensitivity and 95% specificity. A multiply injured child is likely to be in the scanner having other anatomic studies done in any case and no other study has been shown to be better for detection of unstable cervical spine injury. This test detects all significant injuries to the cervical spine and has very few false-positives as opposed to MRI scanning, which overcalls the injury 1 in 4 times.

TREATMENT
The initial management of spine and spinal cord injuries in children is similar to that in adults. The cervical spine should be immobilized in the field by the emergency medical technicians. In cases of acute spinal cord injury, some data support the acute infusion of a bolus of high-dose (30 mg/kg) methylprednisolone followed by a 23 hr infusion (5.4 mg/kg/hr). The data for this treatment in children are controversial.

Surgical management of unstable spinal injuries must be tailored to the patient’s age. For occipitocervical dislocations, early surgery with fusion from the occiput to C2 or C3 should be performed, even in babies older than 6 mo. Fixation of the subaxial spine must be tailored to the size of the pedicles and other osseous structures of the developing axial skeleton.

PREVENTION
The most important aspect of the care of spinal cord injuries in children relates to injury prevention. In this regard, the use of appropriate child restraints in automobiles is the most important precaution. In older children and adolescents, rules against spear tackling in football and the “First First, First Time Program” from the Think First Foundation aimed at adolescents diving into swimming pools and natural water areas are important ways to help prevent severe cervical spinal cord injuries.

Bibliography is available at Expert Consult.
Bibliography
Bibliography

Transverse myelitis (TM) is a condition characterized by rapid development of both motor and sensory deficits at any level of the spinal cord. TM presents acutely as either partial or complete cord involvement and is defined as evidence of spinal cord inflammation by an MRI-documented enhancing lesion, or CSF pleocytosis (>10 cells), or increased immunoglobulin G index. The progression is rapid and the time to maximal disability is more than 4 hr and fewer than 21 days. It has multiple causes and tends to occur in 2 distinct contexts. Small children, 3 yr of age and younger, develop spinal cord dysfunction over hours to a few days. They have a history of an infectious disease, usually of viral origin, or of an immunization within the few weeks preceding the development of their neurologic difficulties. The clinical loss of function is often severe and may seem complete. Although a slow recovery (weeks to months) is common in these cases, it is likely to be incomplete. The likelihood of independent ambulation in these small children is approximately 40%. The pathologic findings of perivascular infiltration with mononuclear cells imply an infectious or inflammatory basis. Overt necrosis of spinal cord may rarely be seen.

In older children, the syndrome is somewhat different. Although the onset is also rapid with a nadir in neurologic function occurring between 2 days and 2 wk, recovery is more rapid and more likely to be complete. Pathologic or imaging examination shows acute demyelination. **CLINICAL MANIFESTATIONS**

TM is often preceded within the previous 1-3 wk by a mild nonspecific illness, minimal trauma, or perhaps an immunization. In both forms the patient shows or complains of discomfort or overt pain in the neck or back, depending on the level of the lesion. The most common involved segments are in the thoracic region. Depending on its severity, the condition progresses to numbness, anesthesia, ataxia, areflexia, and motor weakness in the truncal and appendicular musculature at or distal to the lesion. Paralysis begins as flaccidity (paraparesis, tetraparesis), but over a few weeks spasticity develops and is evident by hyperreflexia and clonus. Rarely is the weakness unilateral. Urinary retention is an early finding; incontinence occurs later in the course. Most have sensory loss manifest as anesthesias, paresthesias, or allodynia. Other findings may include priapism and vision loss (neuromyelitis optica), as well as spinal shock and subsequent autonomic dysreflexia.

The differential diagnosis includes demyelinating disorders, overt meningitis, spinal cord infarction, or mass lesions such as bony distorsion, abscess, and spine and spinal cord tumors (Table 606-1).

**DIAGNOSTIC EVALUATION**

MRI with and without contrast enhancement is essential to rule out a mass lesion requiring neurosurgical intervention. In both conditions, T1-weighted images of the spine at the anatomic level of involvement may be normal or may show distention of the spinal cord. In the infantile form, T2-weighted images show high signal intensity that extends over multiple segments. In the adolescent form, the high signal intensity may be limited to 1 or 2 segments. A limited degree of contrast enhancement after the administration of gadolinium is expected, especially in the infantile form, and denotes an inflammatory condition (Fig. 606-10). MRI of the brain is also indicated and shows evidence of other foci of demyelination in at least 30% of patients; in these patients and those with encephalopathy, acute disseminated encephalomyelitis must be considered (Fig. 606-11).

After a mass lesion associated with spinal cord compression or complete subarachnoid column block from spinal cord swelling have been ruled out, a lumbar puncture is indicated. In both forms of disease, the number of mononuclear cells is usually elevated. The level of CSF protein may be elevated or normal. CSF should be analyzed for myelin basic protein and immunoglobulin levels, which are usually elevated in TM. The presence of inflammatory cells is essential for the diagnosis of TM.

Because one of the most important possibilities for this condition is neuromyelitis optica (NMO; Devic syndrome) the serum of all patients should be analyzed for the NMO antibody. This test is positive in most patients with NMO (see Chapter 600.2). NMO is associated with bilateral optic neuritis and recurrent or long segment TM (≥3 segments). NMO may involve any spinal segment in addition to the brainstem or conus medullaris and cauda equina (myeloradiculitis). As in adults with

Chapter 606  Spinal Cord Disorders 2959

Figure 606-10 Transverse myelitis. A, Sagittal T2-weighted image demonstrates a longitudinal hyperintense spinal cord lesion spanning three vertebral segments (arrows). B, On an axial T2-weighted image, the lesion involves more than two-thirds of the cord’s cross-sectional area (arrow). C, Sagittal T1-weighted postcontrast image shows an enhancing area within the lesion (arrow). (From Ajtai B, Lindzen E, Masdeu JC: Structural imaging: magnetic resonance imaging and computed tomography. In Daroff RB, Fenichel GM, Jankovic J, Mazziotta JC, editors: Bradley’s neurology in clinical practice, ed 6. Philadelphia, 2012, WB Saunders, Fig. 33A.96.)

Figure 606-11 Acute disseminated encephalomyelitis. Sagittal T2-weighted image shows a diffuse hyperintense lesion spanning the length of the cervical cord (arrows). Note the enlarged caliber of the cord, which is a result of swelling. (From Ajtai B, Lindzen E, Masdeu JC: Structural imaging: magnetic resonance imaging and computed tomography. In Daroff RB, Fenichel GM, Jankovic J, Mazziotta JC, editors: Bradley’s neurology in clinical practice, ed 6. Philadelphia, 2012, WB Saunders, Fig. 33A.95.)

TM, older children with the condition should have serum studies sent for autoimmune disorders, especially systemic lupus erythematosus.

TREATMENT
There are no standards for the treatment of TM. Available evidence suggests that modulation of the immune response may be effective in decreasing the severity and duration of the condition. The use of high-dose steroids, particularly methylprednisolone, is the initial approach to treatment of childhood forms of TM. If there is a poor response to high-dose steroids, other therapeutic approaches include intravenous immunoglobulin, plasma exchanges, rituximab, and cyclophosphamide.

Follow-up of children with TM often reveals poor ambulation, continued bowel or bladder symptoms and dysesthesias.

Bibliography is available at Expert Consult.

606.7 Spinal Arteriovenous Malformations
Harold L. Rekate

Arteriovenous malformations of the spinal cord are rare lesions in children. Only about 60 patients younger than age 18 yr are treated in the United States each year. These lesions are complex. Despite their rarity there are multiple subtypes, which require different treatment strategies. Patients commonly present with back or neck pain, depending on the segments of the spinal cord involved, and they may experience the insidious onset of motor and sensory disturbances. Sudden onset of paraplegia secondary to hemorrhage has been reported. Occasionally, patients present with subarachnoid hemorrhage without overt neurologic deficits, similar to the presentation associated with cerebral aneurysms. In some cases, bruits are audible upon auscultation over the bony spine.

DIAGNOSTIC EVALUATION
When a spinal arteriovenous malformation is suspected, MRI of the spinal cord is first needed to make the diagnosis and to obtain a general idea of the location of the lesion. MR angiography or CT angiography may provide further information, but formal catheter angiography of the spinal cord is needed to obtain an adequate understanding of the complex anatomy of the lesion and to plan the intervention.

TREATMENT
Open microsurgery had been the mainstay of treatment for spinal cord arteriovenous fistulas and arteriovenous malformations. With the rapid development of interventional techniques, the percentage of patients undergoing microsurgery has decreased from 70% to approximately 30%. Stereotactic radiosurgery may be used adjunctively. Treatment of these complex lesions requires the commitment of an organized neurovascular treatment program.
Bibliography

The term neuromuscular disease defines disorders of the motor unit and excludes influences on muscular function from the brain, such as spasticity. The motor unit has 4 components: a motor neuron in the brainstem or ventral horn of the spinal cord; its axon, which together with other axons forms the peripheral nerve; the neuromuscular junction; and all muscle fibers innervated by a single motor neuron. The size of the motor unit varies among different muscles and with the precision of muscular function required. In large muscles, such as the glutei and quadriceps femoris, hundreds of muscle fibers are innervated by a single motor neuron; in small, finely tuned muscles, such as the stapedius or the extraocular muscles, a 1:1 ratio can prevail.

The motor unit is influenced by suprasegmental or upper motor neuron control that alters properties of muscle tone, precision of movement, reciprocal inhibition of antagonistic muscles during movement, and sequencing of muscle contractions to achieve smooth, coordinated movements. Suprasegmental impulses also augment or inhibit the monosynaptic stretch reflex; the corticospinal tract is inhibitory upon this reflex.

Diseases of the motor unit are common in children. These neuromuscular diseases may be genetically determined, congenital or acquired, acute or chronic, and progressive or static. Because specific therapy is available for many diseases and because of genetic and prognostic implications, precise diagnosis is important; laboratory confirmation is required for most diseases because of overlapping clinical manifestations.

Many chromosomal loci are identified with specific neuromuscular diseases as a result of genetic linkage studies and the isolation and cloning of a few specific genes. In some cases, such as Duchenne muscular dystrophy, the genetic defect is a deletion of nucleotide sequences and is associated with a defective protein product, dystrophin. In other cases, such as myotonic muscular dystrophy, the genetic defect is an expansion or repetition, rather than a deletion, in a codon (a set of 3 consecutive nucleotide repeats that encodes for a single amino acid), with many copies of a particular codon (in this example they are also associated with abnormal messenger RNA). Some diseases manifest as autosomal dominant and autosomal recessive traits in different pedigrees; these distinct mendelian genotypes can result from different genetic mutations on different chromosomes (neuronal myopathy) or from small differences in the same gene at the same chromosomal locus (myotonia congenita), despite many common phenotypic features and shared histopathologic findings in a muscle biopsy specimen. Among the several clinically defined mitochondrial myopathies, specific mitochondrial DNA deletions and transfer RNA point mutations are recognized. The inheritance patterns and chromosomal and mitochondrial loci of common neuromuscular diseases affecting infants and children are summarized in Table 608-1 in Chapter 608.

### CLINICAL MANIFESTATIONS

Examination of the neuromuscular system includes an assessment of muscle bulk, tone, and strength. Tone and strength should not be confused: Passive tone is range of motion around a joint; active tone is physiologic resistance to movement. Head lag when an infant is pulled to a sitting position from supine is a sign of weakness, not of low tone. Hypotonia may be associated with normal strength or with weakness; enlarged muscles may be weak or strong; thin, wasted muscles may be weak or have unexpectedly normal strength. The distribution of these components is of diagnostic importance. In general, myopathies follow a proximal distribution of weakness and muscle wasting (with the notable exception of myotonic muscular dystrophy); neuropathies are generally distal in distribution (with the notable exception of juvenile spinal muscular atrophy; Table 607-1). Involvement of the face, tongue, palate, and extraocular muscles provides an important distinction in the differential diagnosis. Tendon stretch reflexes are generally lost in neuromopathies and in motor neuron diseases and are diminished but preserved in myopathies (Table 607-1). A few specific clinical features are important in the diagnosis of some neuromuscular diseases. Fasciculations of muscle, which are often best seen in the tongue, are a sign of denervation. Sensory abnormalities indicate neuropathy. Fatigable weakness is characteristic of neuromuscular junctional disorders. Myotonia is specific for a few myopathies.

Some features do not distinguish myopathy from neuropathy. Muscle pain or myalgias are associated with acute disease of either myopathic or neurogenic origin. Acute dermatomyositis and acute polyneuropathy (Guillain-Barré syndrome) are characterized by myalgias. Muscular dysstrophies and spinal muscular atrophies are not associated with muscle pain. Myalgias also occur in several metabolic diseases of muscle and in ischemic myopathy, including vascular diseases such as dermamyositis. Myalgias denote the acuity, rather than the nature, of the process, so that progressive but chronic diseases, such as muscular dystrophy and spinal muscular atrophy, are not painful but acute stages of inflammatory myopathies and acute denervation of muscle often do present with muscular pain and tenderness to palpation. Contractures of muscles, whether present at birth or developing later in the course of an illness, occur in both myopathic and neurogenic diseases.

Infant boys who are weak in late fetal life and in the neonatal period often have undescended testes. The testes are actively pulled into the scrotum from the anterior abdominal wall by a pair of cords that consist of smooth and striated muscle called the gubernaculum. The gubernaculum are weakened in many congenital neuromuscular diseases, including spinal muscular atrophy, myotonic muscular dystrophy, and many congenital myopathies.

The thorax of infants with congenital neuromuscular disease often has a funnel shape, and the ribs are thin and radiolucent as a result of intercostal muscle weakness during intrauterine growth. This phenomenon is characterized found in infantile spinal muscular atrophy but also occurs in myotubular myopathy, neonatal myotonic dystrophy, and other disorders (Fig. 607-1). Because of the small muscle mass, birthweight may be low for gestational age.

Generalized hypotonia and motor developmental delay are the most common presenting manifestations of neuromuscular disease in infants and young children (Table 607-2). These features can also be expressions of neurologic disease, endocrine and systemic metabolic diseases, and Down syndrome, or they may be nonspecific neuromuscular expressions of malnutrition or chronic systemic illness (Table 607-3). A prenatal history of decreased fetal movements and intrauterine growth retardation is often found in patients who are symptomatic at birth. Developmental disorders tend to be of slow onset and are progressive. Acute flaccid paralysis in older infants and children has a different differential diagnosis (Table 607-4).
LABORATORY FINDINGS

Serum Enzymes

Several lysosomal enzymes are released by damaged or degenerating muscle fibers and may be measured in serum. The most useful of these enzymes is creatine kinase (CK), which is found in only 3 organs and may be separated into corresponding isozymes: MM for skeletal muscle, MB for cardiac muscle, and BB for brain. Serum CK determination is not a universal screening test for neuromuscular disease because many diseases of the motor unit are not associated with elevated enzymes. The CK level is characteristically elevated in certain diseases, such as Duchenne muscular dystrophy, and the magnitude of increase is characteristic for particular diseases.

### Molecular Genetic Markers

Many DNA markers of hereditary myopathies, including the muscular dystrophies, and neuropathies are available from leukocytes in blood samples. If the clinical manifestations suggest a particular disease, these tests can provide a definitive diagnosis and not subject the child to more-invasive procedures, such as muscle biopsy. Other molecular markers are available only in muscle biopsy tissue.

### Nerve Conduction Velocity

Motor and sensory nerve conduction velocity may be measured electrophysiologically by using surface electrodes. Neuropathies of various types are detected by decreased conduction. The site of a traumatic nerve injury may also be localized. The nerve conduction value at birth is about half of the mature value achieved by age 2 yr. Tables are available for normal values at various ages in infancy, including for preterm infants. Because the nerve conduction velocity study measures only the fastest conducting fibers in a nerve, 80% of the total nerve fibers must be involved before slowing in conduction is detected.

### Electromyography

Electromyography (EMG) requires insertion of a needle into the belly of a muscle and recording of the electric potentials in various states of contraction. It is less useful in pediatrics than in adult medicine, in part because of technical difficulties in recording these potentials in young children and in part because the best results require the patient’s cooperation for full relaxation and maximal voluntary contraction of a muscle. Many children are too frightened to provide such cooperation. Characteristic EMG patterns distinguish denervation from myopathic involvement. The specific type of myopathy is not usually definitively diagnosed, but certain specialized myopathic conditions, such as myotonia, may be demonstrated. An EMG can transiently raise the serum CK level.

EMG combined with repetitive electrical stimulation of a motor nerve supplying a muscle to produce tetany is useful in demonstrating myasthenic decremental responses. Small muscles, such as the abductor digiti quinti of the hypothenar eminence, are used for such studies. Additional specialized tests, such as single myofiber EMG, may provide supplementary evidence in selected cases, but are performed only in large neuromuscular centers.

### Imaging of Muscle and Central Nervous System

Ultrasoundography, CT scans, and, more often, MRI are used to image muscle in many neuromuscular diseases. Although these methods are not always definitively diagnostic, in experienced hands, they provide a supplementary means of following the progression of disease over time. MRI is quite useful in identifying inflammatory myopathies of immune (dermatomyositis) or infectious (viral, bacterial, parasitic) origin. MRI is the study of choice to image the spinal cord, if a tumor or other structural lesion of the spinal cord is suspected as the cause of muscular dysfunction, and nerve roots and plexus (e.g., brachial plexus). Brain MRI is indicated in some myopathies, such as the congenital muscular dystrophies, in which cerebral malformations often accompany the myopathy because the mutated gene responsible is expressed in both muscle and the developing brain.

### Muscle Biopsy

The muscle biopsy is traditionally the most important and specific diagnostic study of most neuromuscular disorders, if the definitive diagnosis of a hereditary disease is not provided by molecular genetic testing in blood. Not only are neurogenic and myopathic processes distinguished, but also the type of myopathy and specific enzymatic deficiencies may be determined. The vastus lateralis (quadriceps femoris) is the muscle that is most commonly sampled. The deltoid muscle should be avoided in most cases because it normally has a 60-80% predominance of type I fibers so that the distribution patterns of fiber types are difficult to recognize. Muscle biopsy is a simple outpatient procedure that may be performed under local anesthesia with or without femoral nerve block. Needle biopsies are preferred in some centers but are not percutaneous and require an incision in the skin similar to open biopsy; numerous samples must be taken to conduct an adequate examination of the tissue, and they provide inferior specimens. The volume of tissue from a needle biopsy is usually not adequate for all required studies, including supplementary biochemical studies, such as mitochondrial respiratory chain enzymes; a small, clean, open biopsy is therefore advantageous.

Histochemical studies of frozen sections of the muscle are obligatory in all pediatric muscle biopsies because many congenital and metabolic myopathies cannot be diagnosed from paraffin sections using conventional histologic stains. Immunohistochemistry is a useful supplement in some cases, such as for demonstrating dystrophin in suspected Duchenne muscular dystrophy or merosin in congenital muscular dystrophy. A portion of the biopsy specimen should be fixed for potential electron microscopy, but ultrastructure has additional diagnostic value only in selected cases. Interpretation of muscle biopsy samples is complex and should be performed by an experienced pathologist. A portion of frozen muscle tissue should also be routinely saved for possible biochemical analysis (mitochondrial cytopathies, carnitine palmitoyltransferase, acid maltase).

Immunocytochemical reactivities can be applied to formalin-fixed, paraffin-embedded sections and do not require frozen sections. Some reactivities, such as slow and fast myosin, can distinguish fiber types and hence substitute for myofibrillar adenosine triphosphatase histochemical stains in frozen sections. An increasing number of sarcolemmal regional proteins can be demonstrated that are specific for
each of the various muscular dystrophies and include the dystrophins, merosin, sarcoglycans, and dystroglycans. Ryanodine receptors, important in myasthenia gravis and in malignant hyperthermia, also now can be demonstrated. In addition, immunocytochemical reactivities can distinguish the various types of inflammatory cells in autoimmune myopathies, including T and B lymphocytes and macrophages.

  - Acute intermittent porphyria
  - Vasculitic neuropathy
  - Critical illness neuropathy
- Lymphomatous neuropathy

### Nerve Biopsy

The most commonly sampled nerve is the sural nerve, a pure sensory nerve that supplies a small area of skin on the lateral surface of the foot. Whole or fascicular biopsy specimens of this nerve may be taken. When the sural nerve is severed behind the lateral malleolus of the ankle, regeneration of the nerve occurs in more than 90% of cases, so that permanent sensory loss is not experienced. The sural nerve is often involved in many neuropathies whose clinical manifestations are predominantly motor.

Electron microscopy is performed on most nerve biopsy specimens because many morphologic alterations cannot be appreciated at the resolution of a light microscope. Teased fiber preparations are sometimes useful in demonstrating segmental demyelination, axonal swellings, and other specific abnormalities, but these time-consuming procedures are not done routinely. Special stains may be applied to ordinary frozen or paraffin sections of nerve biopsy material to demonstrate myelin, axoplasm, and metabolic products.

The molecular genetic identification of the specific mutation in many of the hereditary motor and sensory neuropathies, determined from blood samples, has rendered the nerve biopsy much less important. For which the etiology remains elusive despite genetic and electrophysiological testing.

### Cardiac Assessment

Cardiac evaluation is important if myopathy is suspected because of involvement of the heart in muscular dystrophies and in inflammatory and metabolic myopathies. Electrocardiography often detects early cardiomyopathy or conduction defects that are clinically asymptomatic. At times, a more complete cardiac work-up, including echocardiography and consultation with a pediatric cardiologist, is indicated. Serial pulmonary function tests also should be performed in muscular dystrophies and in other chronic or progressive diseases of the motor unit.

**From Hughes RAC, Camblath DR: Guillain-Barré syndrome, Lancet 366:1653–1666, 2005**

**Bibliography is available at Expert Consult.**
Bibliography
A heterogeneous group of congenital neuromuscular disorders is known as the congenital myopathies (Tables 608-1 and 608-2). Most of these disorders have subcellular abnormalities that can be demonstrated only by muscle biopsy, by means of histochemistry and electron microscopy. In others, the muscle biopsy abnormality is not a subcellular anatomic defect but an aberration in the ratio and sizes of specific myofiber types. A genetic basis is demonstrated in many of the congenital myopathies, and molecular genetic testing from blood samples may confirm the diagnosis without muscle biopsy.

Most congenital myopathies are nonprogressive conditions, but some patients show slow clinical deterioration accompanied by additional changes in their muscle histology. In some congenital myopathies, such as severe neonatal nemaline myopathy, the clinical expression can be life-threatening because of dysphagia and respiratory and/or cardiac insufficiency. Cardiomyopathy develops in some patients with congenital myopathies (Table 608-3). Most of the diseases in the category of congenital myopathies are hereditary; others are sporadic. Although clinical features, including phenotype, can raise a strong suspicion of a congenital myopathy, the definitive diagnosis is determined by the histopathologic findings in the muscle biopsy specimen. In conditions for which the defective gene has been identified, the diagnosis may be established by the specific molecular analysis of the suspected gene expressed in lymphocytes. The morphologic and histochemical abnormalities differ considerably from those of the muscular dystrophies, spinal muscular atrophies, and neuropathies. Many are reminiscent of the embryologic development of muscle, thus suggesting possible defects in the genetic regulation of muscle development.

Congenital myopathies often show closer genetic relationships than previously appreciated between entities that have quite distinct pathologic phenotypes in the muscle biopsy and also distinctiveness in clinical expression with a degree of overlap. For example, mutation of the tropomyosin-3 (TPM3) gene is one of the well-documented etiologies of nemaline myopathy, but identical genetic mutations of this gene are more recently also shown to be capable of causing isolated congenital fiber-type disproportion without nemaline rods, cap myopathy, centro-nuclear (“myotubular”) myopathy, and central core/minicore disease.

Continued
fusion of myoblasts to form myotubes. *Herculin* (also known as *MYF6*) and *MYOD1* are the other 2 myogenic genes. *Myf5* cannot support myogenic differentiation without *myogenin*, *MyoD*, and *MYF6*. Each of these 4 genes can activate the expression of at least 1 other and, under certain circumstances, can autoactivate as well. Another recently discovered gene known as *myomaker* also facilitates myoblast fusion. The expression of *MYF5* and of *herculin* is transient in early ontogenesis but returns later in fetal life and persists into adult life.

The human locus of the *MYOD1* gene is on chromosome 11, very near to the domain associated with embryonal rhabdomyosarcoma. The genes *Myf5* and *herculin* are on chromosome 12, and *myogenin* is on chromosome 1. The myogenic genes are activated during muscle regeneration, recapitulating the developmental process; *MyoD* in particular is required for myogenic stem cell (satellite cell) activation in adult muscle. *PAX3*, *PAX7*, and *WNT3a* genes also play important roles in myogenesis and interact with each of the 4 basic genes mentioned above. Another gene, *myostatin*, is a negative regulator of muscle development by preventing myocytes from differentiating. The precise integrative roles of the myogenic genes in developmental myopathies are not yet fully defined.

The myogenic genes are important not only for fetal myogenesis but also for regeneration of muscle at any age, particularly in degenerative diseases such as muscular dystrophies and autoimmune inflammatory myopathies and in injuries of muscle secondary to trauma or to toxins. Satellite cells in mature muscle that mediate regeneration have the same somitic origin as embryonic muscle progenitor cells, but the genes that regulate them differ. *Pax3* and *Pax7* mediate the migration of primitive myoblast progenitors from the myotomes of the somites to their peripheral muscle sites in the embryo, but only 1 of 2 *Pax7* genes continues to act postnatally for satellite cell survival. Then it, too, no longer is required after the juvenile period for muscle satellite (i.e., stem) cells to become activated for muscle regeneration.

### 608.1 Myotubular Myopathy
**Centronuclear Myopathy**
Harvey B. Sarnat

The term *myotubular myopathy* is a misnomer because it implies maturational arrest of fetal muscle during the myotubular stage of development at 8–15 wk of gestation. It was based on the morphologic appearance of myofibers as a row of central nuclei and mitochondria within a core of cytoplasm, with contractile myofilaments forming a cylinder around this core (Fig. 608-1). These morphologically abnormal myofibers are not true fetal myotubes, however; hence the more neutral and descriptive term *centronuclear myopathy* is preferred.

**PATHOGENESIS**

The common pathogenesis involves loss of myotubularin protein, leading to structural and functional abnormalities in the organization of T-tubules and sarcoplasmic reticulum and defective excitation-contraction coupling.

**CLINICAL MANIFESTATIONS**

Fetal movements can decrease in late gestation. Polyhydramnios is a common complication because of pharyngeal weakness of the fetus and inability to swallow amniotic fluid. At birth, affected infants have a thin muscle mass involving axial, limb girdle, and distal muscles; severe generalized hypotonia; and diffuse weakness. Respiratory efforts may be ineffective, requiring ventilatory support. Gavage feeding may be required because of weakness of the muscles of sucking and deglutition. The tests are often undescended. Facial muscles may be weak, but infants do not have the characteristic facies of myotonic dystrophy. P toesis may be a prominent feature. Ophthalmoplegia is observed in a few cases. The palate may be high. The tongue is thin, but fasciculations are not seen. Tendon stretch reflexes are weak or absent.

Myotubular myopathy is not associated with cardiomyopathy (mature cardiac muscle fibers normally have central nuclei), but one report describes complete atrioventricular block without cardiomyopathy in a patient with confirmed X-linked myotubular myopathy. Congenital anomalies of the central nervous system or of other systems are not associated. A single patient with progressive dementia was reported, who had a mutation removing the start signal of exon 2. Patients with much milder symptoms or a much later age of onset with mutations in the same gene are now known. Some of these are manifesting carriers.

**LABORATORY FINDINGS**

Serum levels of creatine kinase (CK) are normal. Electromyography does not show evidence of denervation; results are usually normal or show minimal nonspecific myopathic features in early infancy. Nerve conduction velocity may be slow but is usually normal. The

ECG, electrocardiogram.

Bibliography
Histochemical stains for oxidative enzymatic activity and glycogen reveal a central distribution as in fetal myotubes. The cylinder of myofibrils shows mature histochemical differentiation with adenosine triphosphatase stains. The connective tissue of muscle spindles, blood vessels, intramuscular nerves, and motor end plates is mature. Ultrastructural features other than those that define the disease are also mature. Electron microscopy shows disorganized triads and focal loss of myofilaments. Vimentin and desmin show strong immunoreactivity in muscle fibers in congenital centronuclear myopathy and no demonstrable activity in normal term neonatal muscle. The molecular genetic marker in blood is available also for early prenatal diagnosis if suspicion is strong because of family history. Table 608-4 distinguishes centronuclear myopathy from other congenital myopathies.

**GENETICS**

At least 5 genes are involved in this disorder and account for approximately 80% of patients. These include mutations in myotubularin (MTM1 gene) with X-linked severe manifestations; dynamin 2 (DNM2) with autosomal dominant or sporadic occurrence; amphiphysin 2 (BIN1) and titin (TTN) mutations with autosomal recessive inheritance and ryanodine receptor 1 (RYR1), with autosomal recessive or sporadic occurrence.

X-linked recessive inheritance is the most common trait in this disease affecting boys. The mothers of affected infants are clinically asymptomatic, but their muscle biopsy specimens show minor alterations. Genetic linkage on the X chromosome has been localized to the Xq28 site, a locus different from the Xp21 gene of Duchenne and Becker muscular dystrophies. A deletion in the responsible MTM1 gene has been identified. It encodes a protein called myotubularin. This gene belongs to a family of similar genes encoding enzymatically active and inactive forms of phosphatidylinositol-3-phosphatases that form dimers. MTM1, dynamin-2, and amphiphysin all are localized to the T-tubule wall in triads. This crucial region is where the action potential releases a signal to the ryanodine receptor to release calcium. The pathogenesis is in the regulation of enzymatic activity and binding to other proteins induced by dimer interactions. Although only a single MTM1 gene is involved, 5 distinct point mutations and many different alleles, as well as large duplications, can produce the same clinical disease. Mutations in the dynamin-2 protein result in an autosomal dominant form of centronuclear myopathy and may account for up to half of all patients with centronuclear myopathy, but these cases usually are mild and might not manifest clinically until adult life as diffuse, slowly progressive weakness and generalized muscular pseudohypertrophy.

Other *rarer centronuclear myopathies* also are known; some are autosomal recessive and affect both sexes and others are sporadic and of unknown genetic origin. The recessive forms are sometimes divided into an early-onset form with or without ophthalmoplegia and a late-onset form without ophthalmoplegia.

**TREATMENT**

Only supportive and palliative treatment is presently available. Progressive scoliosis may be treated by long posterior fusion. Genetic and neuropathologic studies of X-linked centronuclear (“myotubular”) myopathy have led to effective gene therapy in mice and in dogs, so that even after a single dose the animals are more ambulatory and have much improved weakness. Gene replacement therapy in this disease is now being studied in humans.

**PROGNOSIS**

Approximately 75% of severely affected neonates with the X-linked disease die within the 1st few wk or mo of life. Survivors do not experience a progressive course but have major physical handicaps, rarely walk, and remain severely hypotonic. Late-onset and especially autosomal dominant forms have a much better prognosis, often with mild static weakness.

_Bibliography is available at Expert Consult._
Bibliography
### 608.2 Congenital Muscle Fiber-Type Disproportion

Harvey B. Sarnat

Congenital muscle fiber-type disproportion (CMFTD) occurs as an isolated congenital myopathy but also develops in association with various unrelated disorders that include nemaline rod disease, Krabbe disease (globoid cell leukodystrophy) early in the course before expression of the neuropathy, cerebellar hypoplasia and certain other brain malformations, fetal alcohol syndrome, some glycogenoses, multiple sulfatase deficiency, Lowe syndrome, rigid spine myopathy, and some infantile cases of myotonic muscular dystrophy. CMFTD should, therefore, be regarded as a syndrome, unless a specific genetic mutation is confirmed.

### PATHOGENESIS

The association of CMFTD with cerebellar hypoplasia suggests that the pathogenesis may be an abnormal suprasegmental influence on the developing motor unit during the stage of histochemical differentiation of muscle between 20 and 28 wk of gestation. Muscle fiber types and growth are determined by innervation and are mutable even in adults. Although CMFTD does not actually correspond with any normal stage of development, it appears to be an embryologic disturbance of fiber type differentiation and growth.

### CLINICAL MANIFESTATIONS

As an isolated condition not associated with other diseases, CMFTD is a nonprogressive disorder present at birth. Patients have generalized hypotonia and weakness, but the weakness is usually not severe and respiratory distress and dysphagia are rare. Contractures are present at birth in 25% of patients. Poor head control and developmental delay for gross motor skills are common in infancy. Walking is usually achieved until 18-24 mo but is eventually achieved. Because of the hypotonia, subluxation of the hips can occur. Muscle bulk is reduced. The muscle wasting and hypotonia are proportionately greater than the weakness, and the child may be stronger than expected during examination. Cardiomyopathy is a rare complication.

The facies of children with CMFTD often raise suspicion, especially if the child is referred for assessment of developmental delay and hypotonia. The head is dolichocephalic, and facial weakness is present. The palate is usually high arched. Thin muscles of the trunk and extremities give a thin, wasted appearance. The phenotype is very similar to that of nemaline myopathy that also includes CMFTD as part of the pathologic picture. Patients do not complain of myalgias. The clinical course is nonprogressive.

### LABORATORY FINDINGS

Serum CK, electrocardiogram, electromyography, and nerve conduction velocity results are normal in simple CMFTD. If other diseases are associated, laboratory investigation of those conditions discloses the specific features.

### DIAGNOSIS

CMFTD is diagnosed by muscle biopsy that shows disproportion in size and relative ratios of histochemical fiber types: Type I fibers are uniformly small, and type II fibers are hypertrophic; type I fibers are more numerous than type II fibers. Degeneration of myofibers and other primary myopathic features are absent. The biopsy is diagnostic at birth. Table 608-2 lists the features that distinguish CMFTD from other congenital myopathies.

### GENETICS

Many cases of simple CMFTD are sporadic, although autosomal recessive inheritance is well documented in some families and an autosomal dominant trait is suspected in others. The genetic basis is heterogeneous in hereditary forms; a mutation in the insulin receptor gene at 19p13.2 is reported. Translocation t(10;17) was seen in 1 family. X-linked transmission with linkage to Xp23.12-p11.4 and Xq13.1-q22.1 also is described. In 3 unrelated families with CMFTD, a heterozygous missense mutation of the skeletal muscle α-actin gene (ACTA1) was demonstrated, but this genetic defect represents a minority; mutations in TPM3 are a more common genetic finding. As with X-linked myotubular myopathy, large duplications in the TPM3 gene can cause CMFTD. In CMFTD associated with cerebellar hypoplasia, the genetic effect is on cerebellar development and the muscular expression is secondary.

### TREATMENT

No drug therapy is available. Physiotherapy may be helpful for some patients in strengthening muscles that do not receive sufficient exercise in daily activities. Mild congenital contractures often respond well to gentle range-of-motion exercises and rarely require plaster casting or surgery.

*Bibliography is available at Expert Consult.*

### 608.3 Nemaline Rod Myopathy

Harvey B. Sarnat

Nemaline rods (derived from the Greek *nema*, meaning “thread”) are rod-shaped, inclusion-like abnormal structures within muscle fibers. They are difficult to demonstrate histologically with conventional hematoxylin-and-eosin stain, but are easily seen with special stains. They are not foreign inclusion bodies but rather consist of excessive Z-band material with a similar ultrastructure (Fig. 608-2). Chemically, the rods are composed of actin, α-actinin, tropomyosin-3, and the protein nebulin. Nemaline rod formation may be an unusual reaction of muscle fibers to injury because these rod structures have rarely been found in other diseases. They are most abundant in the congenital myopathy known as *nemaline rod disease*. Most rods are within the myofibrils, but intranuclear rods are occasionally demonstrated by electron microscopy. Intranuclear rods occur mainly in neonates with
Bibliography
The head is dolichocephalic, and the palate high arched or even cleft. Muscles of the jaw may be too weak to hold it closed (Fig. 608-4). Decreased fetal movements are reported by the mother, and neonates suffer from hypoxia and dysphagia; arthrogryposis may be present. Infants with severe neonatal and infantile nemaline myopathy have facies and phenotype that are nearly indistinguishable from those of neonatal myotonic dystrophy, but their mothers have normal facies. The juvenile form is the mildest and is not associated with respiratory failure, but the phenotype, including facial involvement, is similar.

**LABORATORY FINDINGS**

Serum CK level is normal or mildly elevated. The muscle biopsy is diagnostic. In addition to the characteristic nemaline rods, it also shows CMFTD or at least fiber type I predominance. In some patients, uniform type I fibers are seen with few or no type II fibers. Focal myofibrillar degeneration and an increase in lysosomal enzymes have been found in a few severe cases associated with progressive symptoms. Intranuclear nemaline rods, demonstrated by electron microscopy, correlate with the most severe neonatal manifestations. Because nemaline bodies can occur in other myopathies, their presence in the muscle biopsy is not pathognomonic in the absence of the supportive clinical manifestations. Adult-onset cases may be associated with monoclonal gammopathy.

**GENETICS**

Autosomal dominant and autosomal recessive forms of nemaline rod disease occur, and an X-linked dominant form in girls also can occur. Nemaline myopathy can be caused by mutation in at least 7 genes, including α-actin, α-tropomyosin, β-tropomyosin, troponin-T, nebulin, coflin-2, and Kelch-like family member (KLML40). The latter causes severe neonatal autosomal recessive nemaline myopathy. The proteins encoded for by all these genes are related to the thin filaments of myofibrils. Dominant nemaline myopathy is most often caused by mutations in ACTA-I or α-tropomyosin (TPM3 at the 1q21–q23 locus); recessive mutations most frequently result from nebulin mutations (2q21.2-q22 locus), which account for about half the cases of nemaline myopathy and are particularly prevalent in Ashkenazi Jews. Some severe weakness; they usually indicate ACTA1 mutations and may coexist with the more usual cytoplasmic rods. Nemaline myopathy caused by ACTA1 mutation is one of a spectrum of “actinopathies.”

Mutations in tropomyosin-2 (TPM2) can cause a congenital myopathy related to nemaline rod myopathy, designated cap myopathy, in which accumulations of distorted myofilaments are focally present on the periphery of fibers. They may coexist with myofibrillar nemaline rods. Somatic mosaicism is demonstrated in TPM2-related nemaline myopathy with cap structures.

**CLINICAL MANIFESTATIONS**

Neonatal, infantile, and juvenile forms of the disease are known. The neonatal form is severe and usually fatal because of respiratory failure since birth. In the infantile form, generalized hypotonia and weakness, which can include bulbar-innervated and respiratory muscles, and a very thin muscle mass are characteristic (Fig. 608-3). The head is dolichocephalic, and the palate high arched or even cleft. Muscles of the jaw may be too weak to hold it closed (Fig. 608-4). Decreased fetal movements are reported by the mother, and neonates suffer from hypoxia and dysphagia; arthrogryposis may be present. Infants with severe neonatal and infantile nemaline myopathy have facies and phenotype that are nearly indistinguishable from those of neonatal myotonic dystrophy, but their mothers have normal facies. The juvenile form is the mildest and is not associated with respiratory failure, but the phenotype, including facial involvement, is similar.

**LABORATORY FINDINGS**

Serum CK level is normal or mildly elevated. The muscle biopsy is diagnostic. In addition to the characteristic nemaline rods, it also shows CMFTD or at least fiber type I predominance. In some patients, uniform type I fibers are seen with few or no type II fibers. Focal myofibrillar degeneration and an increase in lysosomal enzymes have been found in a few severe cases associated with progressive symptoms. Intranuclear nemaline rods, demonstrated by electron microscopy, correlate with the most severe neonatal manifestations. Because nemaline bodies can occur in other myopathies, their presence in the muscle biopsy is not pathognomonic in the absence of the supportive clinical manifestations. Adult-onset cases may be associated with monoclonal gammopathy.

**GENETICS**

Autosomal dominant and autosomal recessive forms of nemaline rod disease occur, and an X-linked dominant form in girls also can occur. Nemaline myopathy can be caused by mutation in at least 7 genes, including α-actin, α-tropomyosin, β-tropomyosin, troponin-T, nebulin, coflin-2, and Kelch-like family member (KLML40). The latter causes severe neonatal autosomal recessive nemaline myopathy. The proteins encoded for by all these genes are related to the thin filaments of myofibrils. Dominant nemaline myopathy is most often caused by mutations in ACTA-I or α-tropomyosin (TPM3 at the 1q21–q23 locus); recessive mutations most frequently result from nebulin mutations (2q21.2-q22 locus), which account for about half the cases of nemaline myopathy and are particularly prevalent in Ashkenazi Jews. Some
mutations in the α-actin gene give rise to a severe neonatal myopathy with masses of exclusively thin filaments, with or without rods. Mutations in tropomyosin-2 can cause a congenital myopathy with nonspecific findings. In α-actin defects both autosomal dominant and recessive varieties occur at the same 1q42.1 locus. The autosomal dominantly inherited defect of β-tropomyosin at 9q13 and the α-tropomyosin defects are rare and account for only 3% of patients with nemaline myopathy. An autosomal recessive tropomyosin-T defect is at locus 19q13 and has been found only in the Amish population, in whom the incidence of nemaline myopathy is as high as 1 in 500, whereas in Australia in non-Amish ethnic groups it is estimated at 1 in 500,000.

**TREATMENT AND PROGNOSIS**

Therapy is supportive. Survivors are confined to an electric wheelchair and are usually unable to overcome gravity. Both proximal and distal muscles are involved. Congenital arthrogryposis can occur and predicts a poor prognosis. Gastrostomy may be needed for chronic dysphagia. In the juvenile form, patients are ambulatory and are able to perform most tasks of daily living. Weakness is not usually progressive, but some patients have more difficulty over time or enter a phase of progressive weakness. Cardiomyopathy is an uncommon complication. Death usually results from respiratory insufficiency, with or without superimposed pneumonia.

**608.4 Central Core, Minicore, and Multicore Myopathies**

*Harvey B. Sarnat*

Central core disease most often manifests itself in children with slow motor development who are hypotonic and have mild weakness especially in the hip girdle; congenital dislocation or dysplasia of the hips may be diagnosed in the neonatal period. In older children, central core disease is an important differential diagnosis of progressive thoracolumbar scoliosis. Central core myopathies are transmitted as either an autosomal dominant or recessive trait and are caused by the same abnormal gene at the 19q13.1 locus. This gene programs the ryanodine receptor (RYR1), a tetrameric receptor that contains a non–voltage-gated calcium channel; it is prevalent in the sarcoplasmic reticulum and especially at the junction of the T-tubule with the cisternae of the sarcoplasmic reticulum. It contains the channel by which calcium is released among the myofilaments. Mutations in the RYR1 gene are also the cause of malignant hyperthermia.

Infantile hypotonia, proximal weakness, muscle wasting, and involvement of facial muscles and neck flexors are the typical features in both the dominant and recessive forms. Contractures of the knees, hips, and other joints are common, and kyphoscoliosis and pes cavus often develop, even without much axial or distal muscle weakness. There is a high incidence of cardiac abnormalities. The course is not progressive, except for the contractures. In one variant, external ophthalmoplegia also is present. Rare cases of minicore myopathy also show hypertrophic cardiomyopathy associated with short-chain acyl-CoA dehydrogenase deficiency.

The disease is characterized pathologically by central cores within muscle fibers in which only amorphous, granular cytoplasm is found with an absence of myofibrils and organelles. Histochemical stains show a lack of enzymatic activities of all types within these cores, as well as absence of contractile proteins (actin and myosin) that form the thin and thick myofilaments. Variants of central cores, called minicores and multicores, are described in some families.

Minicores or multicore are small areas, usually multiple within muscle fibers, that lack mitochondria and show Z-disc streaming. They can be caused by mutations in the gene (SEPN1) for the selenoprotein N, localized to triads, but RYR1 mutations also are reported. The distinction previously made between single and multiple cores in myofibers is now believed to be of little importance and they represent the same basic disease process.

The serum CK value is normal in central core disease except during crises of malignant hyperthermia, which can result in rhabdomyolysis or extensive acute myofiber necrosis (see Chapter 611.2). Central core disease is consistently associated with malignant hyperthermia, which can precede the diagnosis of central core disease. All patients should have special precautions with pretreatment with dantrolene before an anesthetic agent is administered.

**608.5 Myofibrillar Myopathies**

*Harvey B. Sarnat*

Most myofibrillary myopathies are not symptomatic in childhood, but occasionally older children and adolescents show early symptoms of nonspecific proximal and distal weakness. An infantile form also occurs and can cause mild neonatal hypotonia and weakness with disproportionately severe dysphagia and respiratory insufficiency, at times leading to early death. It is not progressive, however, and some patients show improvement in later infancy and early childhood, acquiring the ability to swallow by 3 yr of age. Cardiomyopathy is a complication in a minority.

The diagnosis is by muscle biopsy; some sarcomeres of myofibers have disorganization or dissolution of myofibrils adjacent to other areas of normal sarcomeres within the same fiber. These zones are associated with streaming of the Z bands and focally increased desmin intermediate filaments, myotitin, and αB-crystallin. Immunocytochemical and ultrastructural study of the muscle biopsy tissue is required. Mutation in the desmin gene is implicated as a contributory factor in the etiology of both adult-onset and childhood myofibrillar myopathies, but the primary defect is a mutation in, not just an upregulation of, the αB-crystallin molecule. An associated secondary mitochondrial defect is detected in some patients.

A unique autosomal recessive myopathy in Cree native infants is characterized by severe generalized muscular hypertonia that is not relieved by neuromuscular blockade and hence is myopathic in origin. Most die in infancy of respiratory insufficiency as a result of diaphragmatic involvement. The muscle biopsy shows findings similar to many other myofibrillar myopathies (Fig. 608-5); a novel αB-crystallin gene mutation is the cause.

*Bibliography is available at Expert Consult.*

*Figure 608-5* Electron micrograph of quadriceps femoris muscle biopsy of a 1 mo old native girl with Cree myofibrillar myopathy. Within the same myofiber, some sarcomeres are well formed and others exhibit disarray of the thin and thick myofilaments and fragmentation of Z bands. Mitochondria appear normal (×21,400).

Infants with cerebellar hypoplasia are hypotonic and developmentally delayed, especially in gross motor skills. Muscle biopsy is sometimes performed to exclude a congenital myopathy. A biopsy specimen can show delayed maturation of muscle, fiber-type predominance, or CMFTD. Other malformations of the brain may also be associated with abnormal histochemical patterns, but supratentorial lesions are less likely than brainstem or cerebellar lesions to alter muscle development. Abnormal descending impulses along bulbo-spi nal pathways probably alter discharge patterns of lower motor neurons that determine the histochemical differentiation of muscle at 20–28 wk of gestation. The corticospinal tract does not participate because it is not yet functional during this period of fetal life.

In several congenital muscular dystrophies (see Chapter 608.6), including the Walker-Warburg syndrome, Fukuyama disease, and muscle-eye-brain disease of Santavuori, major cerebral malformations, such as pachygria and lissencephaly, are present. It is clear that in at least some of these cases, the abnormal protein implicated in pathogenesis of the syndrome is expressed in both muscle and brain and is important for both stabilization of muscle and migration of central neurons.

Bibliography is available at Expert Consult.

### 608.7 Amyoplasia

Congenital absence of individual muscles is common and is often asymmetric. A common aplasia is the palmaris longus muscle of the ventral forearm, which is absent in 30% of normal subjects and is fully compensated for by other flexors of the wrist. Unilateral absence of a sternocleidomastoid muscle is one cause of congenital torticollis. Absence of 1 pectoralis major muscle is part of the Poland anomaly.

When innervation does not develop, as in the lower limbs in severe cases of myelomeningocele, muscles can fail to develop. In sacral agenesis, the abnormal somites that fail to form bony vertebrae can also fail to form muscles from the same defective mesodermal plate, a disorder of induction resulting in segmental amyoplasia. Skeletal muscles of the extremities fail to differentiate from embryonic myomeres if the long bones do not form. Absence of 1 long bone, such as the radius, is associated with variable aplasia or hypoplasia of associated muscles, such as the flexor carpi radialis. End-stage neurogenic atrophy of muscle is sometimes called amyoplasia, but this use is semantically incorrect.

Generalized amyoplasia usually results in fetal death, and liveborn neonates rarely survive. A mutation in 1 of the myogenic genes is the suspected etiology because of genetic knockout studies in mice, but it has not been proven in humans.

### 608.8 Muscular Dysgenesis (Proteus Syndrome Myopathy)

Proteus syndrome is a disturbance of cellular growth involving ectodermal and mesodermal tissues, representing a cellular mosaicism. The genetic defect is a mutation in the AKT1 gene, of the same genetic family as AKT3, which causes hemimegalencephaly; indeed many cases of Proteus syndrome also have hemimegalencephaly. These genes participate in the mammalian target of rapamycin pathway. Proteus syndrome also manifests as asymmetric overgrowth of the extremities, verrucous cutaneous lesions, angiomas of various types, thickening of bones, and excessive growth of muscles without weakness. Severe seizures, beginning in neonates, are uncommon. Histologically, the muscle demonstrates a unique muscular dysgenesis. Abnormal zones are adjacent to zones of normal muscle formation and do not follow anatomic boundaries.

Bibliography is available at Expert Consult.

### 608.9 Benign Congenital Hypotonia

**Benign congenital hypotonia** is not a disease, but it is a descriptive term for infants or children with nonprogressive hypotonia of unknown origin. The hypotonia is not usually associated with weakness or developmental delay, although some children acquire gross motor skills more slowly than normal. Tendon stretch reflexes are normal or hypactive. There are no cranial nerve abnormalities, and intelligence is normal.

The diagnosis is one of exclusion (see Table 607-2 in Chapter 607) after results of laboratory studies, including muscle biopsy and imaging of the brain with special attention to the cerebellum, are normal. Muscle biopsy is deferred in some mild cases to follow the clinical evolution over time, but the diagnosis in these infants is more provisional. No known molecular genetic basis for this syndrome has been identified. Table 607-3 in Chapter 607 lists the differential diagnosis.

The prognosis is generally good; no specific therapy is required. Contractures do not develop. Physical therapy might help achieve motor milestones (walking) sooner than expected. Hypotonia persists into adult life. The disorder is not always as “benign” as its name implies because a common complication is recurrent dislocation of joints, especially the shoulders. Excessive motility of the spine can result in stretch injury, compression, or vascular compromise of nerve roots or of the spinal cord. These are particular hazards for patients who perform gymnastics or who become circus performers because of agility of joints without weakness or pain.

### 608.10 Arthrogryposis

**Arthrogryposis multiplex congenita** is not a disease but is a descriptive term that signifies multiple congenital contractures and is heterogeneous in etiology (see Chapter 682).

The term dystrophy means abnormal growth, derived from the Greek trophē, meaning "nourishment." A muscular dystrophy is distinguished from all other neuromuscular diseases by 4 obligatory criteria: it is a primary myopathy, it has a genetic basis, the course is progressive, and degeneration and death of muscle fibers occur at some stage in the
Duchenne muscular dystrophy (DMD) is the most common hereditary neuromuscular disease affecting all races and ethnic groups. Its characteristic clinical features are progressive weakness, intellectual impairment, hypertrophy of the calves, and proliferation of connective tissue in muscle. The incidence is 1 in 3,600 liveborn infant boys. This disease is inherited as an X-linked recessive trait. The abnormal gene is at the Xp21 locus and is one of the largest genes. Becker muscular dystrophy (BMD) is a disease that is fundamentally similar to DMD, with a genetic defect at the same locus, but clinically it follows a milder and more protracted course.

CLINICAL MANIFESTATIONS

Infant boys are rarely symptomatic at birth or in early infancy, although some are mildly hypotonic. Early gross motor skills, such as rolling over, sitting, and standing, are usually achieved at the appropriate ages or may be mildly delayed. Poor head control in infancy may be the first sign of weakness. Distinctive facies are not an early feature because facial muscle weakness is a late event; in later childhood, a "transverse" or horizontal smile may be seen. Walking is often accomplished at the normal age of approximately 12 mo, but hip girdle weakness may be seen in subtle form as early as the 2nd yr. Toddlers might assume a lordotic posture when standing to compensate for gluteal weakness. An early Gowers sign is often evident by age 3 yr and is fully expressed by age 5 or 6 yr (see Fig. 590-5 in Chapter 590). A Trendelenburg gait, or hip waddle, appears at this time. Common presentations in toddlers include delayed walking, falling, toe walking, and trouble running or walking upstairs, developmental delay, and, less often, malignant hyperthermia after anesthesia.

The length of time a patient remains ambulatory varies greatly. Some patients are confined to a wheelchair by 7 yr of age; most patients continue to walk with increasing difficulty until age 10 yr without orthopedic intervention. With orthotic bracing, physiotherapy, and sometimes minor surgery (Achilles tendon lengthening), most are able to walk until age 12 yr. Ambulation is important not only for postponing the psychologic depression that accompanies the loss of an aspect of personal independence but also because scoliosis usually does not become a major complication as long as a patient remains ambulatory, even for as little as 1 hr per day; scoliosis often becomes rapidly progressive after confinement to a wheelchair.

The relentless progression of weakness continues into the 2nd decade. The function of distal muscles is usually relatively well enough preserved, allowing the child to continue to use eating utensils, a pencil, and a computer keyboard. Respiratory muscle involvement is expressed as a weak and ineffective cough, frequent pulmonary infections, and decreasing respiratory reserve. Pharyngeal weakness can lead to episodes of aspiration, nasal regurgitation of liquids, and an airy or nasal voice quality. The function of the extraocular muscles remains well preserved. Incontinence due to anal and urethral sphincter weakness is an uncommon and very late event.

Contractures most often involve the ankles, knees, hips, and elbows. Scoliosis is common. The thoracic deformity further compromises pulmonary capacity and compresses the heart. Scoliosis usually progresses more rapidly after the child becomes nonambulatory and may be uncomfortable or painful. Enlargement of the calves (pseudohypertrophy) and wasting of thigh muscles are classic features. The enlargement is caused by hypertrophy of some muscle fibers, infiltration of muscle by fat, and proliferation of collagen. After the calves, the next most common site of muscular hypertrophy is the tongue, followed by muscles of the forearm. Fasciculations of the tongue do not occur. The voluntary sphincter muscles rarely become involved.

Unless ankle contractures are severe, ankle deep tendon reflexes remain well preserved until terminal stages. The knee deep tendon reflexes may be present until about 6 yr of age but are less brisk than the ankle jerks and are eventually lost. In the upper extremities, the brachioradialis reflex is usually stronger than the biceps or triceps brachii reflexes.

Cardiomyopathy, including persistent tachycardia and myocardial failure, is seen in 50–80% of patients with this disease. The severity of cardiac involvement does not necessarily correlate with the degree of skeletal muscle weakness. Some patients die early of severe cardiomyopathy while still ambulatory; others in terminal stages of the disease have well-compensated cardiac function. Smooth muscle dysfunction, particularly of the gastrointestinal tract, is a minor, but often overlooked, feature.

Intellectual impairment occurs in all patients, although only 20–30% have an IQ <70. The majority have learning disabilities that still allow them to function in a regular classroom, particularly with remedial help. A few patients are profoundly intellectually impaired, but there is no correlation with the severity of the myopathy. Epilepsy is slightly more common than in the general pediatric population. Autism-like behavior may develop but is uncommon. Dystrophin is expressed in brain and retina, as well as in striated and cardiac muscle, though the level is lower in brain than in muscle. This distribution might explain some of the central nervous system manifestations. Abnormalities in cortical architecture and of dendritic arborization may be detected neuropathologically; cerebral atrophy is demonstrated by MRI late in the clinical course. The degenerative changes and fibrosis of muscle constitute a painless process. Myalgias and muscle spasms do not occur. Calcification of muscle is rare.

Death occurs usually at about 18-20 yr of age. The causes of death are respiratory failure during sleep, intractable heart failure, pneumonia, or, occasionally, aspiration and airway obstruction.

In BMD, boys remain ambulatory until late adolescence or early adult life. calf pseudohypertrophy, cardiomyopathy, and elevated serum levels of creatine kinase (CK) are similar to those of patients with DMD. Learning disabilities are less common. The onset of weakness is later in BMD than in DMD. Death often occurs in the mid to late 20s; fewer than half of patients are still alive by age 40 yr; these survivors are severely disabled.

LABORATORY FINDINGS

The serum CK level is consistently greatly elevated in DMD, even in symptomatic stages, including at birth. The usual serum concentration is 15,000–35,000 IU/L (normal <160 IU/L). A normal serum CK level is incompatible with the diagnosis of DMD, although in terminal stages of the disease, the serum CK value may be considerably lower than it was a few years earlier because there is less muscle to degenerate. Other lysosomal enzymes present in muscle, such as aldolase and aspartate aminotransferase, are also increased but are less specific.

Cardiac assessment by echocardiography, electrocardiography (ECG), and radiography of the chest is essential and should be repeated
periodically. After the diagnosis is established, patients should be referred to a pediatric cardiologist for long-term cardiac care.

Electromyography (EMG) shows characteristic myopathic features but is not specific for DMD. No evidence of denervation is found. Motor and sensory nerve conduction velocities are normal.

**DIAGNOSIS**

Polymerase chain reaction (PCR) for the dystrophin gene mutation is the primary test, if the clinical features and serum CK are consistent with the diagnosis. If the blood PCR is diagnostic, muscle biopsy may be deferred, but if it is normal and clinical suspicion is high, the more specific dystrophin immunocytology performed on muscle biopsy sections detects the 30% of cases that do not show a PCR abnormality. Immunohistochemical staining of frozen sections of muscle biopsy tissue detects differences in the rod domain, the carboxyl-terminus (that attaches to the sarcolemma), and the aminoterminus (that attaches to the actin myofilaments) of the large dystrophin molecule, and may be prognostic of the clinical course as Duchenne or Becker disease. More-severe weakness occurs with truncation of the dystrophin molecule at the carboxyl-terminus than at the aminoterminus. The diagnosis should be confirmed by blood PCR or muscle biopsy in every case. Dystroglycans and other sarcolemmal regional proteins, such as merosin and sarcoglycans, also can be measured because they may be secondarily decreased.

The muscle biopsy is diagnostic and shows characteristic changes (Figs. 609-1 and 609-2). Myopathic changes include endomysial connective tissue proliferation, scattered degenerating and regenerating myofibers, foci of mononuclear inflammatory cell infiltrates as a reaction to muscle fiber necrosis, mild architectural changes in still-functional muscle fibers, and many dense fibers. These hypercontracted fibers probably result from segmental necrosis at another level, allowing calcium to enter the site of breakdown of the sarcolemmal membrane and trigger a contraction of the whole length of the muscle fiber. Calcifications within myofibers are correlated with secondary β-dystroglycan deficiency.

The decision about whether muscle biopsy should be performed to establish the diagnosis sometimes presents problems. If there is a family history of the disease, particularly in the case of an involved brother whose diagnosis has been confirmed, a patient with typical

![Figure 609-1](image1.png)

**Figure 609-1** Muscle biopsy of a 4 yr old boy with Duchenne muscular dystrophy. Both atrophic and hypertrophic muscle fibers are seen, and some fibers are degenerating (deg). Connective tissue (c) between muscle fibers is increased (hematoxylin and eosin, x400).

![Figure 609-2](image2.png)

**Figure 609-2** Dystrophin is demonstrated by immunohistochemical reactivity in the muscle biopsies of a normal term male neonate (A), a 10 yr old boy with limb-girdle muscular dystrophy (B), a 6 yr old boy with Duchenne muscular dystrophy (C), and a 10 yr old boy with Becker muscular dystrophy (D). In the normal condition, and also in non–X-linked muscular dystrophies in which dystrophin is not affected, the sarcolemmal membrane of every fiber is strongly stained, including atrophic and hypertrophic fibers. In Duchenne dystrophy, most myofibers express no detectable dystrophin, but a few scattered fibers known as revertant fibers show near-normal immunoreactivity. In Becker muscular dystrophy, the abnormal dystrophin molecule is thin, with pale staining of the sarcolemma, in which reactivity varies not only between myofibers but also along the circumference of individual fibers (x250).
clinical features of DMD and high concentrations of serum CK probably does not need to undergo biopsy. The result of the PCR might also influence whether to perform a muscle biopsy. A first case in a family, even if the clinical features are typical, should have the diagnosis confirmed to ensure that another myopathy is not masquerading as DMD. The most common muscles sampled are the vastus lateralis (quadriceps femoris) and the gastrocnemius.

GENETIC ETIOLOGY AND PATHOGENESIS

Despite the X-linked recessive inheritance in DMD, approximately 30% of cases are new mutations, and the mother is not a carrier. The female carrier state usually shows no muscle weakness or any clinical expression of the disease, but affected girls are occasionally encountered, usually having much milder weakness than boys. These symptomatic girls are explained by the Lyon hypothesis in which the normal X chromosome becomes inactivated and the one with the gene deletion is active (see Chapter 80). The full clinical picture of DMD has occurred in several girls with Turner syndrome in whom the single X chromosome must have had the Xp21 gene deletion.

The asymptomatic carrier state of DMD is associated with elevated serum CK values in 80% of cases. The level of increase is usually in the magnitude of hundreds or a few thousand but does not have the extreme values noted in affected males. Prepubertal girls who are carriers of the dystrophy also have increased serum CK values, with highest levels at 8-12 yr of age. Approximately 20% of carriers have normal serum CK values. If the mother of an affected boy has normal CK levels, it is unlikely that her daughter can be identified as a carrier by measuring CK. Muscle biopsy of suspected female carriers can detect an additional 10% in whom serum CK is not elevated; a specific genetic diagnosis using PCR on peripheral blood is definitive. Some female carriers suffer cardiomyopathy without weakness of striated muscles.

A 427-kDa cytoskeletal protein known as dystrophin is encoded by the gene at the Xp21.2 locus. This gene contains 79 exons of coding sequence and 2.5 Mb of DNA, 10 times larger than the next largest gene yet identified. This subsarcomembral protein attaches to the sarcosomal membrane overlying the A and M bands of the myofibrils and consists of 4 distinct regions or domains: the amino terminus contains 250 amino acids and is related to the N-actin binding site of α-actinin; the second domain is the largest, with 2,800 amino acids, and contains many repeats, giving it a characteristic rod shape; a third, cytokeletal-rich domain is related to the carboxyl-terminus of α-actinin; and the final carboxyl-terminal domain of 400 amino acids is unique to dystrophin and to a dystrophin-related protein encoded by chromosome 6. "Dystrophin deficiency" at the sarcolemma disrupts the membrane cytoskeleton and leads to loss secondarily of other components of the cytoskeleton.

The molecular defects in the dystrophinopathies vary and include intragenic deletions, duplications, or point mutations of nucleotides. Approximately 65% of patients have deletions; approximately 10% exhibit duplications while approximately 10% have point mutations or smaller rearrangements. The size or site of the intragenic abnormality does not always correlate well with the phenotypic severity; in both Duchenne and Becker forms the mutations are mainly near the middle of the gene, involving deletions of exons 46-51. Phenotypic or clinical variations are explained by the alteration of the translational reading frame of messenger RNA (mRNA), which results in unstable, truncated dystrophin molecules and severe, classic DMD; mutations that preserve the reading frame still permit translation of coding sequences further downstream on the gene and produce a semisufficient dystrophin, expressed clinically as BMD. An even milder form of adult-onset disease, formerly known as quadriceps myopathy, is also caused by an abnormal dystrophin molecule. The clinical spectrum of the dystrophinopathies not only includes the classic Duchenne and Becker forms but also ranges from a severe neonatal muscular dystrophy to asymptomatic children with persistent elevation of serum CK levels >1,000 IU/L.

Analysis of the dystrophin protein requires a muscle biopsy and is demonstrated by Western blot analysis or in tissue sections by immunohistochemical methods using either fluorescence or light microscopy of antidystrophin antisera (see Fig. 609-2). In classic DMD, levels of <3% of normal are found, but in BMD, the molecular weight of dystrophin is reduced to 20-90% of normal in 80% of patients, but in 15% of patients the dystrophin is of normal size but reduced in quantity, and 5% of patients have an abnormally large protein caused by excessive duplications or repeats of codons. Selective immunoreactivity of different parts of the dystrophin molecule in sections of muscle biopsy material distinguishes the Duchenne and Becker forms (Fig. 609-3). The demonstration of deletions and duplications also can be made from blood samples by the more rapid PCR, which identifies as many as 98% of deletions by amplifying 18 exons but cannot detect duplications. The diagnosis can thus be confirmed at the molecular genetic level from either the muscle biopsy material or from peripheral blood, although as many as 30% of boys with DMD or BMD have a false-normal blood PCR; all cases of dystrophinopathy are detected by muscle biopsy.

The same methods of DNA analysis from blood samples may be applied for carrier detection in female relatives at risk, such as sisters and cousins, and to determine whether the mother is a carrier or whether a new mutation occurred in the embryo. Prenatal diagnosis is possible as early as the 12th wk of gestation by sampling chorionic villi for DNA analysis by Southern blot or PCR and is confirmed in aborted fetuses with DMD by immunohistochemistry for dystrophin in muscle.

TREATMENT

There is no medical cure for this disease. Much can be done to treat complications and to improve the quality of life of affected children. Cardiac decompensation often responds initially well to digoxin. Pulmonary infections should be promptly treated. Patients should avoid contact with children who have obvious respiratory or other contagious illnesses. Immunizations for influenza virus and other routine vaccinations are indicated.

Preservation of a good nutritional state is important. DMD is not a vitamin-deficiency disease, and excessive doses of vitamins should be avoided. Adequate calcium intake is important to minimize osteoporosis in boys confined to a wheelchair, and fluoride supplements may also be given, particularly if the local drinking water is not fluoridated. Because sedentary children burn fewer calories than active children and because depression is an additional factor, these children tend to eat excessively and gain weight. Obesity makes a patient with myopathy even less functional because part of the limited reserve muscle strength is dissipated in lifting the weight of excess subcutaneous adipose tissue. Dietary restrictions with supervision may be needed.

Physiotherapy delays but does not always prevent contractures. At times, contractures are actually useful in functional rehabilitation. If contractures prevent extension of the elbow beyond 90 degrees and the muscles of the upper limb no longer are strong enough to overcome gravity, the elbow contractures are functionally beneficial in fixing an otherwise flail arm and in allowing the patient to eat and write. Surgical correction of the elbow contracture may be technically feasible, but the result may be deleterious. Physiotherapy contributes little to muscle strengthening because patients usually are already using their entire reserve for daily function, and exercise cannot further strengthen involved muscles. Excessive exercise can actually accelerate the process of muscle fiber degeneration.

Special vigilance should be maintained in watching for progressive scoliosis, which should be treated early by orthopedists using external braces or corsets and occasionally by surgeons. Scoliosis often becomes rapidly progressive once the patient is confined to a wheelchair.

Another recommended treatment of patients with DMD involves the use of prednisone, prednisolone, deflazacort, or other steroids. Glucocorticoids decrease the rate of apoptosis or programmed cell death of myotubes during ontogeny and can decelerate the myofiber necrosis in muscular dystrophy. Strength usually improves initially, but the long-term complications of chronic steroid therapy, including
dystrophin protein. The shortened protein has been demonstrated to appear in muscle biopsies after treatment with these agents.

Bibliography is available at Expert Consult.

609.2 Emery-Dreifuss Muscular Dystrophy
Harvey B. Sarnat

Emery-Dreifuss muscular dystrophy, also known as scapuloperoneal or scapulohumeral muscular dystrophy, is a rare X-linked recessive dystrophy. The usual locus of its associated genetic abnormality is on the long arm within the large Xq28 region that includes other mutations that cause myotubular myopathy, neonatal adrenoleukodystrophy, and the Bloch-Sulzberger type of incontinentia pigmenti; it is far from the gene for DMD on the short arm of the X chromosome. Another, rarer form of Emery-Dreifuss dystrophy is transmitted as an autosomal dominant trait and is localized at 1q. This form can manifest quite late, in adolescence or early adult life, although the muscular and cardiac symptoms and signs are similar, and sudden death from ventricular fibrillation is a risk.
Bibliography
Clinical manifestations begin at between 5 and 15 yr of age, but many patients survive to late adult life because of the slow progression of the disease’s course. A rarer severe infantile presentation also is documented. Muscles do not exhibit pseudohypertrophy. Contractures of elbows and ankles develop early, and muscle becomes wasted in a scapulohumeraloperoneal distribution. Facial weakness does not occur; this disease is thus distinguished clinically from autosomal dominant scapulohumeral and scapuloperoneal syndromes of neuromuscular origin. Myotonia is absent. Intellectual function is normal. Dilated cardiomyopathy is severe and is often the cause of death, more commonly from conduction defects such as atrial fibrillation/flutter and sudden ventricular fibrillation than from intractable myocardial failure. Stroke is another complication, secondary to the cardiac arrhythmia. The serum CK value is only mildly to moderately elevated, further distinguishing this disease from other X-linked recessive muscular dystrophies. Nonspecific myofiber necrosis and endomysial fibrosis are seen in the muscle biopsy. Many centronuclear fibers and selective histochi- 

tical type I muscle fiber atrophy can cause confusion with myotonic dystrophy.

GENETICS

The defective gene in the X-linked form is called EMD or EDMD and encodes a protein, emerin. Unlike other dystrophies in which the defective gene is expressed at the sarcolemmal membrane, emerin is expressed at the inner nuclear membrane; this protein stabilizes the nuclear membrane against the mechanical stresses that occur during muscular contraction. It interacts with Nesprin-1 and Nesprin-2 genes, also critical for nuclear membrane integrity. Complete deletion of EDMD occurs in approximately 25% of cases and results from an inversion in the Xq28 region; total absence of emerin is demonstrated by both Western blotting and immunoreactivity in tissue sections. Another gene, LMNA, at the 1q21 locus, is linked to the nuclear envelope and encodes lamin A and C, sometimes termed laminopathy. This genetic mutation causes an identical clinical phenotype to EMD defects, except that both sexes are affected and it is transmitted as either an autosomal dominant or recessive trait. Most EDMD deletions are null mutations, whereas most LMNA alterations are mainly missense mutations with a minority being nonsense or out-of-frame mutations. Desmin protein also may be mutated and seen to be abnormally expressed in the muscle biopsy. Homozygous nonsense mutations in these lamin A/C genes are lethal owing to cardiomyopathy and conduc-

tion disturbances.

DIAGNOSIS AND INVESTIGATIONS

In suspected cases, emerin deficiency may be demonstrated not only in the muscle biopsy by immunoreactivity and Western blotting tech-

iques but also in a variety of other tissues, including circulating lymphocytes in peripheral blood, exfoliative buccal mucosal cells, and skin fibroblasts. Emerin is absent in varying proportions in female carriers. Genetic testing of the specific genes also is available. Patients should all have careful cardiac evaluation, including electrocardiogram and echocardiogram. Serum CK should be measured because it may be moderately elevated; though nonspecific, it provides a baseline for comparison with future measurements. Muscle MRI of the glutei and lower extremities may be helpful, particularly in LMNA mutations. EMG is not definitively diagnostic, but it provides a serial means of following the progression of the myopathy. Muscle biopsy is diagnostic from the onset of symptoms. In the differential diagnosis, an Emery-Dreifuss–like syndrome with joint contractures, mild weakness, and later-onset cardiac symptoms is caused by FHL1 mutations of myofi-

dricular myopathy, but reducing bodies are absent. Treatment should be supportive, with special attention to cardiac conduction defects, and can require medications or a pacemaker. Implantable cardioverter-defibrillators are now available and have prevented sudden death in some patients with Emery-Dreifuss muscular dystrophy.

Bibliography is available at Expert Consult.

609.3 Myotonic Muscular Dystrophy

Harvey B. Sarnat

Myotonic dystrophy (Steinert disease) is the second most common muscular dystrophy in North America, Europe, and Australia, having an incidence varying from 1 in 100,000 to 1 in 300,000 in the general population. It is inherited as an autosomal dominant trait. Classic myotonic dystrophy (type 1) (DM1) is caused by a CTG trinucleotide expansion on chromosome 19q13.3 in the 3′ untranslated region of DMPK, the gene that encodes a serine-threonine protein kinase. Type 2 (DM2) is associated with unstable CCTG tetranucleotide repeat expansion on chromosome 3q21 of an intron of the zinc finger 9 protein gene. A third, late form (DM3) is identified, at locus 15q21-q24.

Myotonic dystrophy is an example of a genetic defect causing dys-

tion in multiple organ systems. Not only is striated muscle severely affected, but smooth muscle of the alimentary tract and uterus is also involved, cardiac function is altered, and patients have multiple and variable endocrinopathies, immunologic deficiencies, cataracts, dys-

morphic facies, increased risk for malignancies, intellectual impair-

ment, and other neurologic abnormalities.

CLINICAL MANIFESTATIONS

DM1 becomes symptomatic at any age, but DM2 is rarely expressed in infancy or early childhood. In the usual clinical course, excluding the severe neonatal form, DM1 infants can appear almost normal at birth, or facial wasting and hypotonia can already be early expressions of the disease. The facial appearance is characteristic, consisting of an inverted V-shaped upper lip, thin cheeks, and scalloped, concave temporalis muscles (Fig. 609-4). The head may be narrow, and the palate is high and arched because the weak temporal and pterygoid muscles in late fetal life do not exert sufficient lateral forces on the developing head and face. Weakness is mild in the 1st few yr. Progressive wasting of distal muscles becomes increasingly evident, particularly involving intrinsic muscles of the hands. The thenar and hypothenar eminences are flat-

tened, and the atrophic dorsal intersosseous leave deep grooves between the fingers. The dorsal forearm muscles and anterior compartment muscles of the lower legs also become wasted. The tongue is thin and atrophic. Wasting of the sternocleidomastoids gives the neck a long, thin, cylindrical contour. Proximal muscles also eventually undergo atrophy, and scapular winging appears. Difficulty with climbing stairs

Figure 609-4 Facial weakness, inverted V–shaped upper lip, and loss of muscle mass in the temporal fossae are characteristic of myotonic muscular dystrophy, even in infancy, as seen in this 8 mo old girl.
Bibliography
and Gowers sign are progressive. Tendon stretch reflexes are usually preserved.

The distal distribution of muscle wasting in myotonic dystrophy is an exception to the general rule of myopathies having proximal and neuromuscular wasting with distal distribution patterns. The muscular atrophy and weakness in myotonic dystrophy are slowly progressive throughout childhood and adolescence and continue into adulthood. It is rare for patients with myotonic dystrophy to lose the ability to walk even in late adult life, although splints or bracing may be required to stabilize the ankles.

Myotonia, a characteristic feature shared by a few other myopathies, does not occur in infancy and is usually not clinically evident or occurs electromyographically evident until about age 5 yr. Exceptional patients develop it as early as age 3 yr. Myotonia is a slow relaxation of muscle after contraction, regardless of whether that contraction was voluntary or was induced by a stretch reflex or electrical stimulation. During physical examination, myotonia may be manifested by asking the patient to make tight fists and then to quickly open the hands (grip myotonia; Fig. 609-5). It may be induced by striking the thenar eminence with a rubber percussion hammer (percussion myotonia), and it may be detected by watching the involuntary drawing of the thumb across the palm. Myotonia can also be demonstrated in the tongue by pressing the edge of a wooden tongue blade against its dorsal surface and by observing a deep furrow that disappears slowly. The severity of myotonia does not necessarily parallel the degree of weakness, and the weakest muscles often have only minimal myotonia. Myotonia is not a painful muscle spasm. Myalgias do not occur in myotonic dystrophy.

The speech of patients with myotonic dystrophy is often articulated poorly and is slurred because of the involvement of the muscles of the face, tongue, and pharynx. Difficulties with swallowing sometimes occur. Aspiration pneumonia is a risk in severely involved children. Incomplete external ophthalmoplegia sometimes results from extraocular muscle weakness.

Smooth muscle involvement of the gastrointestinal tract results in slow gastric emptying, poor peristalsis, and constipation. Some patients have encopresis associated with anal sphincter weakness. Women with myotonic dystrophy can have ineffective or abnormal uterine contractions during labor and delivery.

Cardiac involvement is usually manifested as heart block in the Purkinje conduction system and arrhythmias (and sudden death) rather than as cardiomyopathy, unlike most other muscular dystrophies. Atrial or ventricular tachyarrhythmias have also resulted in sudden death in adults and older children.

Endocrine abnormalities involve many glands and appear at any time during the course of the disease so that endocrine status must be reevaluated annually. Hypothyroidism is common; hyperthyroidism occurs rarely. Adrenocortical insufficiency can lead to an addisonian crisis even in infancy. Diabetes mellitus is common in patients with myotonic dystrophy; some children have a disorder of insulin release rather than defective insulin production. Onset of puberty may be precocious or, more often, delayed. Testicular atrophy and testosterone deficiency are common in adults and are responsible for a high incidence of male infertility. Ovarian atrophy is rare. Frontal baldness is also characteristic in male patients and often begins in adolescence.

Immunologic deficiencies are common in myotonic dystrophy. The plasma immunoglobulin G level is often low.

Cataracts often occur in myotonic dystrophy. They may be congenital, or they can begin at any time during childhood or adult life. Early cataracts are detected only by slit-lamp examination; periodic examination by an ophthalmologist is recommended. Visual evoked potentials are often abnormal in children with myotonic dystrophy and are unrelated to cataracts. They are not usually accompanied by visual impairment.

About half of the patients with myotonic dystrophy are intellectually impaired, but severe intellectual impairment is unusual. The remainder are of average or occasionally above-average intelligence. Epilepsy is not common. Cognitive impairment might result from accumulations of mutant DM1 mRNA and aberrant alternative splicing in cerebral cortical neurons. A higher than expected incidence of autism occurs in children with DM1.

A severe congenital form of myotonic dystrophy appears in a minority of involved infants born to mothers with symptomatic myotonic dystrophy. All patients with this severe congenital disease to date have had the DM1 form. Clubfoot deformities alone or more extensive congenital contractures of many joints can involve all extremities (arthrogryposis multiplex congenita) and even include the cervical spine. Generalized hypotonia and weakness are present at birth. Facial wasting is prominent. Infants can require gavage feeding or ventilator support for respiratory muscle weakness or apnea. Those requiring ventilation for <30 days often survive, and those with prolonged ventilation have an infant mortality of 25%. Children ventilated for <30 days have better motor, language, and daily activity skills than those requiring prolonged ventilation. One or both leaves of the diaphragm may be nonfunctional. The abdomen becomes distended with gas in the stomach and intestine because of poor peristalsis from smooth muscle weakness. The distention further compromises respiration. Inability to empty the rectum can compound the problem.

LABORATORY FINDINGS

The classic myotonic electromyogram is not found in infants but can appear in toddlers or children in the early school years. The levels of serum CK and other serum enzymes from muscle may be normal or only mildly elevated in the hundreds (never the thousands).

ECG should be performed annually in early childhood. Ultrasound imaging of the abdomen may be indicated in affected infants to determine diaphragmatic function. Radiographs of the chest and abdomen and contrast studies of gastrointestinal motility may be needed.

Endocrine assessment should be undertaken to determine thyroid and adrenal cortical function and to verify carbohydrate metabolism (glucose tolerance test). Immunoglobulins should be examined, and, if needed, more extensive immunologic studies should be performed.

DIAGNOSIS

The primary diagnostic test is a DNA analysis of blood to demonstrate the abnormal expansion of the CTG or CCTG repeat. Prenatal diagnosis also is feasible. The muscle biopsy specimen in older children shows many muscle fibers with central nuclei and selective atrophy of histochemical type I fibers, but degenerating fibers are usually few and widely scattered, and there is little or no fibrosis of muscle. Intramuscular fibers of muscle spindles are also abnormal. In young children with the congenital form of the disease, the biopsy specimen can even appear normal or at least not show myofiber necroses, which is a striking contrast with DMD. In the severe neonatal form of myotonic dystrophy, the muscle biopsy reveals maturation arrested in various stages of

Figure 609-5 The patient was asked to squeeze with both of his hands for several seconds and then suddenly release his grasp, and several seconds passed before full relaxation was achieved, an exam finding known as grip myotonia. (From Hughes BN, Hogue JS, Hsieh DT: Grip and percussion myotonia in myotonic dystrophy type 1, J Pediatr 164:1234, 2014.)
development in some and congenital muscle fiber-type disproportion in others. It is likely that the sarcotendinous membrane of muscle fibers not only has abnormal properties of electrical polarization but is also incapable of responding to trophic influences of the motor neuron. Muscle biopsy is not usually required for diagnosis, which in typical cases can be based on the clinical manifestations, including family history. **Neonatal myotonic dystrophy** must be distinguished from amyoplasia, congenital muscular dystrophy with or without merosin expression, congenital myasthenia gravis, spinal muscular atrophy, and arthrogryposis secondary to oligohydramnios.

**GENETICS**

The genetic defect in myotonic muscular dystrophy is on chromosome 19 at the 19q13 locus. It consists of an expansion of the DM gene that encodes a serine-threonine kinase (DMPK), with numerous repeats of the CTG codon. Expansions range from 50 to >2,000, with the normal alleles of this gene ranging in size from 5-37; the larger the expansion, the more severe the clinical expression, with the largest expansions seen in the severe neonatal form. Rarely, the disease is associated with no detectable repeats, perhaps a spontaneous correction of a previous expansion but a phenomenon still incompletely understood. Another myotonic dystrophy (proximal myotonic myopathy) is a clinical entity linked to at least 2 different chromosomal loci than classic myotonic dystrophy but to 1 locus that shares a common unique pathogenesis in being mediated by a mutant mRNA. Defects in RNA splicing explain the insulin resistance in myotonic dystrophies as well as the myotonia. Clinical and genetic expression can vary between siblings or between an affected parent and child. In the severe neonatal form of the disease, the mother is the transmitting parent in 94% of cases, a fact not explained by increased male infertility alone. Several cases of paternal transmission have been reported. Genetic analysis reveals that symptomatic neonates usually have many more repeats of the CTG codon than do patients with the more classic form of the disease, regardless of which parent is affected. Myotonic dystrophy often exhibits a pattern of **anticipation** in which each successive generation has a tendency to be more severely involved than the previous generation. Prenatal genetic diagnosis of myotonic dystrophy is available.

**Treatment**

There is no specific medical treatment, but the cardiac, endocrine, gastrointestinal, and ocular complications can often be treated. Physiotherapy and orthopedic treatment of contractures in the neonatal form of the disease may be beneficial. Myotonia may improve with exercise (warm-up phenomenon). Cardiac pacemaker implantation might be considered for heart block and antiarrhythmic drugs might be indicated but are needed only rarely in children.

Myotonia may be diminished, and function may be restored by drugs that raise the depolarization threshold of muscle membranes, such as mexiletine, phenytoin, carbamazepine, procainamide, and quinidine sulfate. These drugs also have cardiotropic effects; thus, cardiac evaluation is important before prescribing them. Phenytoin and carbamazepine are used in doses similar to their use as antiepileptics (see Chapter 593.6); serum concentrations of 10-20 µg/mL for phenytoin and 5-12 µg/mL for carbamazepine should be maintained. If a patient's disability is caused mainly by weakness rather than by myotonia, these drugs will be of no value.

**OTHER MYOTONIC SYNDROMES**

Most patients with myotonia have myotonic dystrophy. However, myotonia is not specific for this disease and occurs in several rarer conditions.

**Myotonic chondrodystrophy** (Schwartz-Jampel disease) is a rare congenital disease characterized by generalized muscle hypertrophy and weakness. Dysorphic phenotypical features and the radiographic appearance of long bones are reminiscent of Morquio disease (see Chapter 88), but abnormal mucopolysaccharides are not found. Dwarfism, joint abnormalities, and blepharophimosis are present. Several patients have been the products of consanguinity, suggesting autosomal recessive inheritance. The muscle protein perlecan, encoded by the **SCNA4** gene, a large heparan sulfate proteoglycan of basement membranes and cartilage, is defective in some cases of Schwartz-Jampel disease and explains both the muscular hyperexcitability and the chondrodysplasia.

EMG reveals continuous electrical activity in muscle fibers closely resembling or identical to myotonia. Muscle biopsy reveals nonspecific features of dystrophy.

myopathic features, which are minimal in some cases and pronounced in others. The sarcotubular system is dilated.

**Myotonia congenita (Thomsen disease)** is a channelopathy (Table 609-1) and is characterized by weakness and generalized muscular hypertrophy so that affected children resemble bodybuilders. Myotonia is prominent and can develop at age 2-3 yr, earlier than in myotonic dystrophy. The disease is clinically stable and is apparently not progressive for many years. Muscle biopsy specimens show minimal pathologic changes, and the EMG demonstrates myotonia. Various families are described as showing either autosomal dominant (Thomsen disease) or recessive (Becker disease, not to be confused with BMD or DMD) inheritance. Rarely, myotonic dystrophy and myotonia congenita coexist in the same family. The autosomal dominant and autosomal recessive forms of myotonia congenita have been mapped to the same 7q35 locus. This gene is important for the integrity of chloride channels of the sarcolemmal and T-tubular membranes.

**Paramyotonia** is a temperature-related myotonia that is aggravated by cold and alleviated by warm external temperatures. Patients have difficulty when swimming in cold water or if they are dressed inadequately in cold weather. **Paramyotonia congenita** (Eulenburg disease) is a defect in a gene at the 17q13.1-13.3 locus, the identical locus identified in hyperkalemic periodic paralysis. By contrast with myotonia congenita, paramyotonia is a disorder of the voltage-gated sodium channel caused by a mutation in the α subunit. Myotonic dystrophy also is a sodium channelopathy (see Table 609-1).

In sodium channelopathies, exercise produces increasing myotonia, whereas in chloride channelopathies, exercise reduces the myotonia. This is easily tested during examination by asking patients to close the eyes forcefully and open them repeatedly; it becomes progressively more difficult in sodium channel disorders and progressively easier in chloride channel disorders.

### 609.4 Limb-Girdle Muscular Dystrophies

*Harvey B. Sarnat*

Limb-girdle muscular dystrophies (LGMDs) encompass a heterogeneous group of progressive hereditary muscular dystrophies that mainly affect muscles of the hip and shoulder girdles (Table 609-2). Distal muscles also eventually become atrophic and weak. Hypertrophy of the calves and ankle contractures develop in some forms, causing potential confusion with BMD. Sixteen genetic forms of LGMD are now described, each at a different chromosomal locus and expressing different protein defects. Some include diseases classified with other traditional groups, such as the lamin-A/C defects and expressing different protein defects. Some include diseases classified with other traditional groups, such as the lamin-A/C defects and expressing different protein defects. Some include diseases classified with other traditional groups, such as the lamin-A/C defects and expressing different protein defects.

Bibliography
layers of small vesicles. Regenerating myofibers outnumber degenerating myofibers. These disorders were formerly called hyperCKemia and rippling muscle disease, the latter sometimes confused with myotonia. An autosomal recessive mutation in the calcium-activated chloride channel anocamtin-5 can cause proximal LGMD2.

There is overlap of the group of LGMDs with the congenital muscular dystrophies, such as Walker-Warburg syndrome with POMT, Fukuyama muscular dystrophy with FKRP genetic defects, and Ullrich muscular dystrophy of collagen V1 subunits.

Bibliography is available at Expert Consult.

609.5 Facioscapulohumeral Muscular Dystrophy

Harvey B. Sarnat

Facioscapulohumeral muscular dystrophy, also known as Landouzy-Dejerine disease, is probably not a single disease entity but a group of diseases with similar clinical manifestations. Autosomal dominant inheritance is the rule; genetic anticipation is often found within several generations of a family, the succeeding more severely involved at an earlier age than the preceding. The frequency is 1: 20,000 population. Though the clinical onset is generally in later childhood or adult life, early molecular defects arising during myogenesis are demonstrated in the human fetus. The genetic mechanism in autosomal dominant facioscapulohumeral dystrophy involves deletion of a 3.3-kb tandem repeat (D4Z4) in the subtelomeric region at the 4q35 locus. Several other genes clustered at the 4q35 locus are upregulated in fetuses with facioscapulohumeral dystrophy. D4Z4 acts as a laminadependent insulator exhibiting both enhancer-blocking and barrier activities and displaces the telomere toward the nuclear periphery. A 3.3-kb repeat array at the subtelomeric locus 10q26 is closely homologous, with chromosomal translocation or sequence conversion between these 2 regions, possibly predisposing to the DNA rearrangement causing facioscapulohumeral dystrophy. Approximately 10% of families with this phenotype do not map to the 4q35 locus.

CLINICAL MANIFESTATIONS

Facioscapulohumeral dystrophy shows the earliest and most severe weakness in facial and shoulder girdle muscles. The facial weakness differs from that of myotonic dystrophy; rather than an inverted V–shaped upper lip, the mouth in facioscapulohumeral dystrophy is rounded and appears puckered because the lips protrude. Inability to close the eyes completely in sleep is a common expression of upper facial weakness; some patients have extraocular muscle weakness, although ophthalmoplegia is rarely complete. Facioscapulohumeral dystrophy has been associated with Möbius syndrome on rare occasions. Pharyngeal and tongue weakness may be absent and is never as severe as the facial involvement. Hearing loss, which may be subclinical, and retinal vasculopathy (indistinguishable from Coats disease) are associated features, particularly in severe cases of facioscapulohumeral dystrophy with early-childhood onset.

Scapular winging is prominent, often even in infants. Flattening or even concavity of the deltoid contour is seen, and the biceps and triceps brachii muscles are wasted and weak. Muscles of the hip girdle and thighs also eventually lose strength and undergo atrophy, and Gowers sign and a Trendelenburg gait appear. Contractures of the extremities are rare. Finger and wrist weakness occasionally is the first symptom. Weakness of the anterior tibial and peroneal muscles can lead to footdrop; this complication usually occurs only in advanced cases with severe weakness. Lumbar lordosis and kyphoscoliosis are common complications of axial muscle involvement. Calf pseudohypertrophy is not a usual feature but is described rarely.

Facioscapulohumeral muscular dystrophy can also be a mild disease causing minimal disability. Clinical manifestations might not be expressed in childhood and are delayed into middle adult life. Unlike most other muscular dystrophies, asymmetry of weakness is common. About 30% of affected patients are asymptomatic or show only mild scapular winging and decreased tendon stretch reflexes, of which they were unaware until formal neurologic examination was performed.

LABORATORY FINDINGS

Serum levels of CK and other enzymes vary greatly, ranging from normal or near-normal to elevations of several thousand. An ECG should be performed, although the anticipated findings are usually normal. EMG reveals nonspecific myopathic muscle potentials. Diagnostic molecular testing in individual cases and within families is indicated for prediction.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Molecular genetic diagnosis is the most specific confirmation if clinical suspicion is high, with or without a family history of the disease. Muscle biopsy distinguishes more than one form of facioscapulohumeral dystrophy, consistent with clinical evidence that several distinct diseases are embraced by the term facioscapulohumeral dystrophy. Muscle biopsy and EMG also distinguish the primary myopathy from a neurogenic disease with a similar distribution of muscular involvement. The general histopathologic findings in the muscle biopsy material are extensive proliferation of connective tissue between muscle fibers, extreme variation in fiber size with many hypertrophic as well as atrophic myofibers, and scattered degenerating and regenerating fibers. An “inflammatory” type of facioscapulohumeral muscular dystrophy is also distinguished, characterized by extensive lymphocytic infiltrates within muscle fascicles. Despite the resemblance of this form to inflammatory myopathies, such as polymyositis, there is no evidence of autoimmune disease, and steroids and immunosuppressive drugs do not alter the clinical course. A precise histopathologic diagnosis has important therapeutic implications. Mononuclear cell “inflammation” in a muscle biopsy sample of infants younger than 2 yr old is usually facioscapulohumeral dystrophy or, less often, a congenital muscular dystrophy.

TREATMENT

Physiotherapy is of no value in regaining strength or in retarding progressive weakness or muscle wasting. Footdrop and scoliosis may be treated by orthopedic measures. In selected cases, surgical wiring of the scapulas to the thoracic wall provides improved shoulder stability and abduction of the arm, but brachial plexopathy, frozen shoulder, and scapular fractures are reported complications. Cosmetic improvement of the facial muscles of expression may be achieved by reconstructive surgery, which grafts a fascia lata to the zygomatic muscle and to the zygomatic head of the quadratus labii superioris muscle. Exercise of facial muscles can help minimize secondary disuse atrophy. No effective pharmacologic or genetic treatment is presently available.

Bibliography is available at Expert Consult.

609.6 Congenital Muscular Dystrophies

Harvey B. Sarnat

The term congenital muscular dystrophy is misleading because all muscular dystrophies are genetically determined. It is used to encompass several distinct diseases that have a common characteristic of severe involvement at birth but that, ironically, often follow a more benign clinical course than the early onset and the histopathological changes in the muscle biopsy would suggest. A distinguishing feature of the congenital dystrophies, by contrast with other muscular dystrophies, is a high association with brain malformations, particularly disorders of cortical development such as lissencephaly/pachygyria and polymicrogyria, often complicated by severe epilepsy. Autosomal recessive inheritance is the rule.

CLINICAL MANIFESTATIONS

In several distinct clinical and genetic diseases grouped under the umbrella term congenital muscular dystrophies, infants often have
Bibliography
Bibliography
congenital muscular dystrophy with associated merosin deficiency (LAMA2 mutation at locus 6q22-q23) and Ullrich disease (COL6A1, -A2 and -A3 mutations at 21q22 and 2q37 loci). A protein of the endoplasmic reticulum (SEPN1 mutation at 1p35) is the basis of rigid spine syndrome. Abnormal glycosylation of α-dystroglycan causes Walker-Warburg syndrome (POMT1 mutation at 9q34), muscle-eye-brain disease of Santavuori (POMGnT1 mutation at 1p32), Fukuyama muscular dystrophy (FCMD mutation at 8q31-q33 and 9q31), and congenital muscular dystrophy with secondary merosin deficiency (FKRP mutation at 19q13). Glycosylation defects (dystroglycanopathies) result in defective neuroblast migration in the fetal brain and also can cause dilated cardiomyopathy. The dystroglycan molecule interacts with both proteins of the plasma (sarcemmal) membrane and those of the extracellular matrix and basal lamina not only in muscle but also in brain, where defective dystroglycan and poor glycosylation result in gaps in the pial limiting membrane, a discontinuous glia limitans, causing cobblestone lissencephaly and glioneuronal heterotopia of overmigrated neural cells during formation of the cerebral cortex.

The Fukuyama type of congenital muscular dystrophy is the second most common muscular dystrophy in Japan (after DMD); it has also been reported in children of Dutch, German, Scandinavian, and Turkish ethnic backgrounds. In the Fukuyama variety, severe cardiomyopathy and malformations of the brain usually accompany the skeletal muscle involvement. Signs and symptoms related to these organs are prominent: cardiomegaly and heart failure, intellectual disability, seizures, microcephaly, and failure to thrive.

Central neurologic disease can accompany forms of congenital muscular dystrophy other than Fukuyama disease. Mental and neurologic status is the most variable feature; an apparently normal brain and normal intelligence do not preclude the diagnosis if other manifestations indicate this myopathy. The cerebral malformations that occur are not consistently of one type and vary from severe dysplasias (holoprosencephaly, lissencephaly) to milder conditions (agenesis of the corpus callosum, focal heterotopia of the cerebral cortex and subcortical white matter, cerebellar hypoplasia). Seizures are a frequent complication, as early as the neonatal period, and may include infantile spasms and other severe infantile epilepsies.

Congenital muscular dystrophy is a constant association with cerebral dysgenesis in the Walker-Warburg syndrome and in muscle-eye-brain disease of Santavuori. The neuropathologic findings are those of neuroblast migratory abnormalities in the cerebral cortex, cerebellum, and brainstem. Studies indicate considerably more genetic overlap between Walker-Warburg, Fukuyama, and muscle-eye-brain forms of congenital muscular dystrophy that explain mixed and transitional phenotypes, so that, for example, a Fukutin-related (FKRP) gene can cause a Walker-Warburg or muscle-eye-brain presentation, or POMGnT1 also can produce phenotypes other than classic Walker-Warburg disease.

LABORATORY FINDINGS

Serum CK level is usually moderately elevated from several hundred to many thousand IU/L; only marginal increases are sometimes found. EMG shows nonspecific myopathic features. Investigation of all forms of congenital muscular dystrophy should include cardiac assessment and an imaging study of the brain. Muscle biopsy is essential for the diagnosis, but if there is a high degree of suspicion (e.g., a confirmed genetic defect in a sibling), specific genetic testing might avoid the muscle biopsy.

DIAGNOSIS

Muscle biopsy is diagnostic in the neonatal period or thereafter. An extensive proliferation of endomal collagen envelopes individual muscle fibers even at birth, also causing them to be rounded in cross-sectional contour by acting as a rigid sleeve, especially during contraction. The perimysial connective tissue and fat are also increased, and the fascicular organization of the muscle may be disrupted by the fibrosis. Tissue cultures of intramuscular fibroblasts exhibit increased collagen synthesis, but the structure of the collagen is normal. Muscle fibers vary in diameter, and many show central nuclei, myofibrillar splitting, and other cytoarchitectural alterations. Scattered degenerating and regenerating fibers are seen. No inflammation or abnormal inclusions are found.

Immunocytochemical reactivity for merosin (α, chain of laminin) at the sarcomallem region is absent in approximately 40% of cases and normally expressed in the others (Figs. 609-6 and 609-7).

Figure 609-6 Quadriceps femoris muscle biopsy of a 6 mo old girl with congenital muscular dystrophy associated with merosin (α-laminin) deficiency. A, Histologically, the muscle is infiltrated by a great proliferation of collagenous connective tissue; myofibers vary in diameter, but necrotic fibers are rare. B, Immunocytochemical reactivity for merosin (α-laminin) is absent in all fibers, including the intramuscular myofibers of a muscle spindle seen at bottom. C, Dystrophin expression (rod domain) is normal. Compare with Figures 609-2, 609-3, and 609-7.
Merosin is a protein that binds the sarcolemmal membrane of the myofiber to the basal lamina or basement membrane. Merosin also is expressed in brain and in Schwann cells. The presence or absence of merosin does not always correlate with the severity of the myopathy or predict its course, but cases with merosin deficiency tend to have more severe cerebral involvement. Adhalin (α-dystroglycan) may be secondarily reduced in some cases. Collagen VI is selectively reduced or absent in Ullrich disease because of a mutation in the COL6A1 gene. Mitochondrial dysfunction may be another secondary defect.

**TREATMENT**

Only supportive therapy is available in general. Cyclosporine might correct the mitochondrial dysfunction and muscular apoptosis in collagen VI myopathy. Though no curative treatment is presently available for the congenital muscular dystrophies, a consensus statement on the standard of supportive care was issued at a special workshop in 2009 and published the following year. It covers aspects of various organ systems that could be involved, including neurologic, pulmonary, gastroenterologic, cardiac, orthopedic/rehabilitation, and palliative care.

THYROID MYOPATHIES
See also Chapters 563-568.

Thyrotoxicosis causes proximal weakness and wasting accompanied by myopathic electromyographic changes. Thyroxine binds to myofibrils and, if in excess, impairs contractile function. Hyperthyroidism can also induce myasthenia gravis and hypokalemic periodic paralysis, the latter mainly affecting East Asian males who have a genetic predisposition. Mutation in the gene KCNJ18 may be responsible for altering the potassium channel Kir2.6 in up to one third of cases. Potassium supplementation and propranolol are useful in treating thyrotoxic periodic paralysis.

Hypothyroidism, whether congenital or acquired, consistently produces hypotonia and a proximal distribution of weakness. Although muscle wasting is most characteristic, one form of cretinism, the Kocher-Debré-Sémélaigne syndrome, is characterized by generalized pseudohypertrophy of weak muscles. Infants can have a Herculanean appearance reminiscent of myotonia congenita. The serum creatine kinase (CK) level is elevated in hypothyroid myopathy and returns to normal after thyroid replacement therapy.

Results of muscle biopsy in hypothyroidism reveal acute myopathic changes, including myofiber necrosis and sometimes central cores. In hyperthyroidism, the muscle biopsy specimen shows only mild, non-specific myopathic changes without necrosis of myofibers.

The clinical and pathologic features of hyperthyroid myopathy and hypothyroid myopathy resolve after appropriate treatment of the thyroid disorder. Many of the systemic symptoms of hyperthyroidism, including myopathic weakness and ophthalmoparesis, improve with the administration of β-blockers.

Most patients with primary hyperparathyroidism (see Chapter 573) develop weakness, fatigability, fasciculations, and muscle wasting that is reversible after removal of the parathyroid adenoma. The serum creatine kinase and muscle biopsy remain normal, but the electromyogram can show nonspecific myopathic features. A minority of patients develop myotonia that could be confused with myotonic dystrophy.

STEROID-INDUCED MYOPATHY
Natural Cushing disease and iatrogenic Cushing syndrome from exogenous corticosteroid administration can cause painless, symmetric, progressive proximal weakness, increased serum creatine kinase levels, and a myopathic electromyogram and muscle biopsy specimen (see Chapter 577). Myosin filaments may be selectively lost. The 9α-fluorinated steroids, such as dexamethasone, betamethasone, and triamcinolone, are the most likely to produce steroid myopathy. Dexamethasone alters the abundance of ceramides in myotubes in developing muscle. In patients with dermatomyositis or other myopathies treated with steroids, it is sometimes difficult to distinguish refractoriness of the disease from steroid-induced weakness, especially after long-term steroid administration. Vitamin D is another factor altering muscle metabolism and particularly its sensitivity to insulin; vitamin D deficiency may be accentuated and contribute to steroid myopathy, especially in type 2 diabetic patients and insulin resistance.

All patients who have been taking steroids for long periods develop reversible type II myofiber atrophy; this is a steroid effect but is not steroid myopathy unless it progresses to become a necrotizing myopathy. At greatest risk in the pediatric age group are children requiring long-term steroid therapy for asthma, rheumatoid arthritis, dermatomyositis, lupus, and other autoimmune or inflammatory diseases or who are being treated for leukemia or other hematologic diseases.
In addition to steroids, the drugs listed in Table 610-1 can cause acute or chronic toxic myopathies. An incompletely understood entity known as critical illness myopathy is a progressive weakness of patients with extended illnesses who remain in the intensive care unit; it is associated pathologically with selective loss of thick (myosin) myofilaments; immobility and excessive steroid treatment are believed to be important factors. Various steroids are sometimes used chronically in the treatment of Duchenne muscular dystrophy; they may actually exaggerate the weakness because of steroid myopathy superimposed on the dystrophic process (see Chapter 609).

**Hyperaldosteronism** (Conn syndrome) is accompanied by episodic and reversible weakness similar to that of periodic paralysis. The proximal myopathy can become irreversible in chronic cases. Elevated creatine kinase levels and even myoglobinuria sometimes occur during acute attacks. Arterial hypertension is a frequent manifestation and, in children, aldosterone-secreting adenomas should be considered in the differential diagnosis of idiopathic hypertension. Hereditary primary aldosteronism is due to a mutation in one of the potassium channel genes *KCNJ5* and *GIRK4*.

**Chronic growth hormone excess** (sometimes illicitly acquired by adolescent athletes or seen in acromegaly) produces atrophy of some myofibers and hypertrophy of others, and scattered myofiber degeneration. Despite the augmented protein synthesis induced by growth hormone, it impairs myofibrillar adenosine triphosphatase activity and reduces sarcomemal excitability, with resultant diminished, rather than increased, strength corresponding to the larger muscle mass. It has been used therapeutically in muscular dystrophy with both a positive effect and complications. **Ghrelin** is an intestinal hormone that activates a growth hormone secretagogue receptor and stimulates growth hormone release. In addition to its effect as a “hunger hormone” that involves food intake and fat deposition, it also prevents muscular atrophy by inducing myodifferentiation and myoblast fusion.

Table 611-1 describes the differential diagnosis of metabolic myopathies.

### 611.1 Periodic Paralyses (Potassium-Related) and Other Muscle Channelopathies

Episodic, reversible weakness or paralysis, known as periodic paralysis, is associated with transient alterations in serum potassium levels, usually hypokalemia but occasionally hyperkalemia. All familial forms of periodic paralysis are caused by mutations in genes encoding voltage-gated ion channels in muscle: sodium, calcium, and potassium. Mutations in the CACNA1S voltage-gated calcium (not potassium) channel are the etiology of hypokalemic periodic paralysis. Nonhereditary causes of periodic paralysis are caused by a diverse group of disorders that affect potassium balance (Table 611-2). During

*Deficiency can produce exercise intolerance and myoglobinuria.

attacks, myofibers are electrically unexcitable, although the contractile apparatus can respond normally to calcium. The genetic disorder is inherited as an autosomal dominant trait. It is precipitated in some patients by a heavy carbohydrate meal, insulin, epinephrine including that induced by emotional stress, hyperaldosteronism or hyperthyroidism, administration of amphotericin B, or ingestion of licorice. The defective genes are at the 17q13.1-13.3 locus in \textit{hypokalemic periodic paralysis}, the same as in paramyotonia congenita, and at the 1q31-32 locus in \textit{hyperkalemic periodic paralysis}.

Attacks often begin in infancy, particularly in the hyperkalemic form, and the disease is nearly always symptomatic by 10 yr of age, affecting both sexes equally. Late childhood or adolescence is the more typical age of onset of the hypokalemic form, Andersen-Tawil syndrome, and paramyotonia congenita. Periodic paralysis is an episodic event; patients are unable to move after awakening and gradually recover muscle strength during the next few minutes or hours. All 4 extremities are involved. Muscles that remain active in sleep, such as the diaphragm, extraocular muscles (rapid eye movements), and cardiac muscle, are not affected. Patients are normal between attacks, but in adult life the attacks become more frequent, and the disorder causes progressive myopathy with permanent weakness even between attacks. The usual frequency of attacks in childhood is once a week. The majority of periodic paralyses have been demonstrated and the genes at least partially characterized, but many patients with the same clinical phenotype exhibit no mutations in the identified genes.

### TREATMENT

Paralytic attacks of hypokalemic periodic paralysis are best treated by the oral administration of potassium or even fruit juices that contain potassium. A low sodium intake and the administration of acetazolamide, 125-250 mg bid or tid in school-age children, often is effective in abolishing attacks or at least reducing their frequency and severity. Spironolactone, in a dose of 100-200 mg/day PO in school-age children, may be beneficial as well.

### OTHER MUSCLE CHANNELOPATHIES

Disorders of ion channels other than the well-documented potassium channelopathies also are recognized. A rare, severe \textit{neonatal myotonia} is secondary to a mutation of the voltage-gated sodium-channel \textit{SCN4A} gene; it is unrelated to neonatal myotonic dystrophy, myotonia congenita, or infantile myofibrillar myopathies. This same gene also is responsible for severe neonatal episodic laryngospasm. Mexiletine is effective treatment of the myotonia, but the long-term prognosis remains poor, with death by 2 yr of age. Sodium channel blockers, such as carbamazepine, phenytoin, and procainamide, are alternatives.

Neuromyotonia, a continuous muscle activity of neurogenic origin, may be caused by mutations in genes encoding or antibodies against potassium channels, but is rare in childhood. Schwartz-Jampel disease, resulting from an autosomal recessive trait, involves severe muscle stiffness, myotonia, blepharospasm, and chondroplasia. It becomes symptomatic in the 1st yr of life and is slowly progressive until midadolescence, after which it is stable. It is no longer considered a variant of myotonic dystrophy and is caused by mutation in the \textit{HSPG2} gene that encodes perlecan, the major heparin sulphate proteoglycan of basement membranes. Sodium channel blockers may be useful.

\textit{Bibliography is available at Expert Consult.}

### 611.2 Malignant Hyperthermia

\textbf{Harvey B. Samat}

See also Chapters 61 and 608.4. This syndrome is usually inherited as an autosomal dominant trait. It occurs in all patients with central core disease but is not limited to that particular myopathy. The gene is at the 19q13.1 locus in both central core disease and malignant hyperthermia without this specific myopathy. At least 15 separate mutations in this gene are associated with malignant hyperthermia. The gene programs the ryanodine receptor, a tetrameric calcium release channel in the sarcoplasmic reticulum, in apposition to the voltage-gated calcium channel of the transverse tubule. It occurs rarely in Duchenne and other muscular dystrophies, in various other myopathies, in some children with scoliosis, and in an isolated syndrome not associated with other muscle disease. Affected children sometimes have peculiar facies. All ages are affected, including premature infants whose mothers underwent general anesthesia for cesarean section.

Acute episodes are precipitated by exposure to general anesthetics and occasionally to local anesthetic drugs. Patients suddenly develop extreme fever, rigidity of muscles, and metabolic and respiratory acidosis; the serum CK level rises to as high as 35,000 IU/L. Myoglobinuria can result in tubular necrosis and acute renal failure.

The muscle biopsy specimen obtained during an episode of malignant hyperthermia or shortly afterward is not indicated but shows widely scattered necrosis of muscle fibers known as \textit{rhabdomyolysis}. Between attacks, the muscle biopsy specimen is normal unless there is an underlying chronic myopathy.

It is important to recognize patients at risk of malignant hyperthermia because the attacks may be prevented by administering dantrolene.
Bibliography

sodium before an anesthetic is given. Patients at risk, such as siblings, are identified by the caffeine contracture test: a portion of fresh muscle biopsy tissue in a saline bath is attached to a strain gauge and exposed to caffeine and other drugs; an abnormal spasm is diagnostic. The syndrome-associated receptor also may be demonstrated by immunohistochemistry in frozen sections of the muscle biopsy. The gene defect of the ryanodine receptor is present in 50% of patients; gene testing is available only for this genetic group. This receptor also may be seen in the muscle biopsy by immunoreactivity. Another candidate gene is at the 1q31 locus.

Apart from the genetic disorder of malignant hyperthermia, some drugs can induce acute rhabdomyolysis with myoglobinuria and potential renal failure, but this usually occurs in patients who are predisposed by some other metabolic disease (mitochondrial myopathies). Valproic acid can induce this process in children with mitochondrial cytopathies or with carnitine palmitoyltransferase deficiency.

### 611.3 Glycogenoses
Harvey B. Sarnat

See also Chapter 87.1.

Glycogenosis I (von Gierke disease) is not a true myopathy because the deficient enzyme glycogen-6-phosphatase is not normally present in muscle. Nevertheless, children with this disease are hypotonic and mildly weak for unknown reasons.

Glycogenosis II (Pompe disease) is an autosomal recessively inherited deficiency of the glycotic lysosomal enzyme α-glucosidase (formerly known as acid maltase) that cleaves the α-1,4 and α-1,6 glycosidic linkages. Of the 12 known glycogenoses, type II is the only one with a defective lysosomal enzyme. The defective gene is at locus 17q23, with more than 200 distinct mutations identified. Two clinical forms are described. The infantile form is a severe generalized myopathy and cardiomyopathy. Patients have cardiomegaly and hepatomegaly and are diffusely hypotonic and weak. The serum CK level is greatly elevated. A muscle biopsy specimen reveals a vacuolar myopathy with abnormal lysosomal enzymatic activities such as acid and alkaline phosphatases. Evidence of a secondary mitochondrial cytopathy is often demonstrated; it includes electron microscopic demonstration of paracrystallin structures within muscle mitochondria and low concentrations of respiratory chain enzymes. Death in infancy or early childhood is usual; however, enzyme replacement therapy has improved the outcome.

The late childhood or adult form is a much milder myopathy without cardiac or hepatic enlargement. It might not become clinically expressed until later childhood or early adult life but may be symptomatic as myopathic weakness and hypotonia even in early infancy. Even in late adult-onset acid maltase deficiency, >50% of the patients report difficulties with muscle strength dating from childhood. Ultrastructural evidence of secondary mitochondrial cytopathy also occurs, as with infantile Pompe disease. MRI of muscle may show distinctive changes that differ from other myopathies.

The serum CK level is greatly elevated, and the muscle biopsy findings are diagnostic even in the presymptomatic stage. The diagnosis of glycogenosis II is confirmed by quantitative assay of acid maltase activity in muscle or liver biopsy specimens. A rare variant of the milder form is a much milder myopathy without cardiac or hepatic enlargement. It might not become clinically expressed until later childhood or early adult life but may be symptomatic as myopathic weakness and hypotonia even in early infancy. Even in late adult-onset acid maltase deficiency, >50% of the patients report difficulties with muscle strength dating from childhood. Ultrastructural evidence of secondary mitochondrial cytopathy also occurs, as with infantile Pompe disease. MRI of muscle may show distinctive changes that differ from other myopathies.

### 611.4 Mitochondrial Myopathies
Harvey B. Sarnat

See also Chapters 87.4 and 598.2.

Several diseases involving muscle, brain, and other organs are associated with structural and functional abnormalities of mitochondria, producing defects in aerobic cellular metabolism, the electron transport chain, and the Krebs cycle. Because mitochondria are found in all cells, except mature erythrocytes, the term mitochondrial cytopathy is used preferentially to emphasize the multisystemic nature of these diseases. The structural aberrations are best demonstrated by electron microscopy of the muscle biopsy sample, revealing a proliferation of abnormally shaped cristae, including stacked or whorled cristae and paracrystallin structures that occupy the space between cristae and are formed from CK. Muscle biopsies of neonates, infants, and toddlers show more severe involvement of endothelial cells of intramuscular capillaries than of myofibers, unlike the reverse in adults, but endothelial paracrystallin structures are globular rather than brick shaped as in myofibers. The endoplasmic reticulum becomes abnormally adherent to mitochondria. Similar endothelial mitochondrial alterations are seen in brain in Leigh and other infantile mitochondrial encephalopathies. Histochemical study of the muscle biopsy specimen reveals abnormal clumping of oxidative enzymatic activity and scattered myofibers, with...
Bibliography
loss of cytochrome-c oxidase activity and with increased neutral lipids within myofibers. Raggled red muscle fibers occur in some mitochondrial myopathies, particularly those with a combination of respiratory chain complexes I and IV deficiencies. Accumulations of this membranous material beneath the muscle fiber membrane are best demonstrated by special stains, such as modified Gomori trichrome.

These characteristic histochemical and ultrastructural changes are most consistently seen with point mutations in mitochondrial transfer RNA. The large mitochondrial DNA (mtDNA) deletions of 5 or 7.4 kb (the single mitochondrial chromosome has 16.5 kb) are associated with defects in mitochondrial respiratory oxidative enzyme complexes, if as few as 2% of the mitochondria are affected, but minimal or no morphologic or histochemical changes may be noted in the muscle biopsy specimen, even by electron microscopy; hence, quantitative biochemical studies of the muscle tissue are needed to confirm the diagnosis. Because most of the subunits of the respiratory chain complexes are encoded by nuclear DNA (nDNA) rather than mtDNA, mendelian autosomal inheritance is possible, rather than maternal transmission as with pure mtDNA point mutations. Complex II (succinate dehydrogenase) is the only enzyme complex in which all of its subunits are encoded by nDNA; hence it is histochemically reactive in all mitochondrial diseases with mtDNA point mutations. Serum lactate is elevated in some diseases, and cerebrospinal fluid lactate is more consistently elevated, even if serum concentrations are normal.

Several distinct mitochondrial diseases that primarily affect striated muscle or muscle and brain are identified. These can be divided into the raggled red fiber diseases and non–raggled fiber diseases. The raggled red fiber diseases include Kearns-Sayre, MELAS (mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes) syndrome, MERRF (myoclonic epilepsy with raggled red fibers) syndrome, and progressive external ophthalmoplegia syndromes, which are associated with a combined defect in respiratory chain complexes I and IV. The non–raggled fiber diseases include Leigh encephalopathy and Leber hereditary optic atrophy; they involve complex I or IV alone or, in children, the common combination of defective complexes III and V. Kearns-Sayre syndrome is characterized by the triad of progressive external ophthalmoplegia, pigmentary degeneration of the retina, and onset before age 20 yr. Heart block, cerebellar deficits, and high cerebrospinal fluid protein content are often associated. Visual evoked potentials are abnormal. Patients usually do not experience weakness of the trunk or extremities or dysphagia. Most cases are sporadic.

Chronic progressive external ophthalmoplegia may be isolated or accompanied by limb muscle weakness, dysphagia, and dysarthria. A few patients described as having ophthalmoplegia plus have additional central nervous system involvement. Autosomal dominant inheritance is found in some pedigrees, but most cases are sporadic.

MERRF and MELAS syndromes are other mitochondrial disorders affecting children. The latter is characterized by stunted growth, episodic vomiting, seizures, and recurring cerebral insults causing hemiparesis, hemianopia, or even cortical blindness, and dementia. The disease behaves as a degenerative disorder, and children die within a few years.

Other “degenerative” diseases of the central nervous system that also involve myopathy with mitochondrial abnormalities include Leigh subacute necrotizing encephalopathy (see Chapter 87.4) and cerebrohepatorenal (Zellweger) disease, primarily a peroxisomal disease with secondary mitochondrial alterations (see Chapter 86.2). Another recognized mitochondrial myopathy is cytochrome-c oxidase deficiency. Oculopharyngeal muscular dystrophy is also fundamentally a mitochondrial myopathy.

Mitochondrial depletion syndrome of early infancy is characterized by severely decreased oxidative enzymatic activities in most or all 5 of the complexes; in addition to diffuse muscle weakness, neonates and young infants can show multisystemic involvement and the syndrome occurs in several forms: myopathic; encephalomyopathic; hepatoencephalopathic; and intestinal encephalopathic. Cardiomyopathy and sometimes bullous skin lesions or generalized edema also can occur. Alpers syndrome is genetically homogeneous and is caused by mtDNA deletion and mutations in the POLG1 gene. Several other genes are identified, mostly in later-onset forms; hence mitochondrial depletion is a syndrome and not a single disease. Barth syndrome is an X-linked recessive mitochondrial disorder characterized by cardiomyopathy, myopathy of striated muscle, growth retardation, neutropenia, and high serum and urinary concentrations of 3-methylglutaconic acid.

Many rare diseases with only a few case reports are suspected of being mitochondrial disorders. It is also now recognized that secondary mitochondrial defects occur in a wide range of nonmitochondrial diseases, including inflammatory autoimmune myopathies, Pompe disease, and some cerebral malformations, and also may be induced by certain drugs and toxins, so that interpretation of mitochondrial abnormalities as primary defects must be approached with caution.

mtDNA is distinct from the DNA of the cell nucleus and is inherited exclusively from the mother; mitochondria are present in the cytoplasm of the ovum but not in the head of the sperm, the only part that enters the ovum at fertilization. The rate of mutation of mtDNA is 10 times higher than that of nDNA. The mitochondrial respiratory enzyme complexes each have subunits encoded either in mtDNA or nDNA. Complex II (succinate dehydrogenase, a Krebs cycle enzyme) has 4 subunits, all encoded in nDNA; complex III (ubiquinol or cytochrome-b oxidase) has 9 subunits, only 1 of which is encoded by mtDNA and 8 of which are programmed by nDNA; complex IV (cytochrome-c oxidase) has 13 subunits, only 3 of which are encoded by mtDNA. For this reason, mitochondrial diseases of muscle may be transmitted as autosomal recessive traits rather than by strict maternal transmission, even though all mitochondria are inherited from the mother.

In Kearns-Sayre syndrome, a single large mtDNA deletion has been identified, but other genetic variants are known; in MERRF and MELAS syndromes of mitochondrial myopathy, point mutations occur in transfer RNA.

INVESTIGATIONS

Investigation for mitochondrial cytopathies begins with serum lactate. Lactic acid is not increased in all mitochondrial cytopathies, so that a normal result is not necessarily reassuring; cerebrospinal fluid lactate is increased in some cases in which serum lactate is normal, particularly if there are clinical signs of encephalopathy. Serum 3-methylglutaconic acid often is increased in mitochondrial cytopathies in general, demonstrated in more than 50 different genetic mutations, and hence is a good screening measurement; it rarely is increased in other metabolic diseases. This product also may be increased in urine. Hepatic enzymes (transaminases) should be measured in blood. Cardiac evaluation often is warranted. Molecular markers in blood for the common diseases with known mtDNA point mutations identify many of the mitochondrial cytopathies presenting in adult life or adolescence, but less frequently in children and least in young infants. MRI of the brain may reveal hyperintense lesions of the basal ganglia and MR spectroscopy can demonstrate an increased lactate peak. The muscle biopsy provides the best evidence of all mitochondrial myopathies and should include histochemistry for oxidative enzymes, electron microscopy, and quantitative biochemical assay of respiratory chain enzyme complexes and coenzyme-Q10; muscle tissue also can be analyzed for mtDNA. Many mitochondrial disorders also can affect the Schwann cells and axons of peripheral nerves and present clinically with neuropathy; hence motor and sensory nerve conduction velocities can be measured in selected patients; sural nerve biopsy is required only rarely if neuropathy is the predominant finding and the diagnosis is not evident from other studies.

TREATMENT

There is no effective treatment of mitochondrial cytopathies, but various “cocktails” are often used empirically to try to overcome the metabolic deficits. These include oral carnitine supplements, riboflavin, coenzyme-Q10, ascorbic acid (vitamin C), vitamin E, and other antioxidants. Although some anecdotal reports are encouraging, no controlled studies that prove efficacy have been published.

See Chapter 86.4.

Considered as metabolic organs, skeletal muscles are the most important sites in the body for long-chain fatty acid metabolism because of their large mass and their rich density of mitochondria where fatty acids are metabolized. They are the major source of energy for skeletal muscle during sustained exercise or fasting. Hereditary disorders of lipid metabolism that cause progressive myopathy are an important, relatively common, and often treatable group of muscle diseases. Increased lipid within myofibers is seen in the muscle biopsy of some mitochondrial myopathies and is a constant, rather than an unpredictable, feature of specific diseases. Among the ragged red fiber diseases, Kearns-Sayre syndrome always shows increased neutral lipid, whereas MERRF and MELAS syndromes do not, a useful diagnostic marker for the pathologist. Free fatty acids are converted to acyl-coenzyme A by fatty acyl-coenzyme A synthetases; the resulting long-chain fatty acids bind to carnitine and are transported into mitochondria where β-oxidation is carried out. Disorders of lipid fuel utilization and lipid storage disorders can be divided into defects of transport and oxidation of exogenous fatty acids within mitochondria and defects of endogenous triglyceride catabolism.

Muscle carnitine deficiency is an autosomal recessive disease caused by mutations in the SLC22A5 gene, involving deficient transport of dietary carnitine across the intestinal mucosa. Carnitine is acquired from dietary sources but is also synthesized in the liver and kidneys from lysine and methionine; it is the obligatory carrier of long- and medium-chain fatty acids into muscle mitochondria. The clinical course may be one of sudden exacerbations of weakness or can resemble a progressive muscular dystrophy with generalized proximal myopathy and sometimes facial, pharyngeal, and cardiac involvement. Symptoms usually begin in late childhood or adolescence or may be delayed until adult life. Progression is slow but can end in death.

Serum CK level is mildly elevated. Muscle biopsy material shows vacuoles filled with lipid within muscle fibers in addition to nonspecific changes suggestive of a muscular dystrophy. Mitochondria can appear normal or abnormal. Carnitine measured in muscle biopsy tissue is reduced, but the serum carnitine level is normal.

Treatment stops the progression of the disease and can even restore lost strength if the disease is not too advanced. It consists of special diets low in long-chain fatty acids. Steroids can enhance fatty acid transport. Specific therapy with L-carnitine taken orally in large doses overcomes the intestinal barrier in some patients. Some patients also improve when given supplementary riboflavin, and other patients seem to improve with propranolol.

Systemic carnitine deficiency is a disease of impaired renal and hepatic synthesis of carnitine rather than a primary myopathy. Patients with this autosomal recessive disease experience progressive proximal myopathy and show muscle biopsy changes similar to those of muscle carnitine deficiency; however, the onset of weakness is earlier and may be evident at birth. Endocardial fibroelastosis also can occur. Episodes of acute hepatic encephalopathy resembling Reye syndrome can occur. Hypoglycemia and metabolic acidosis complicate acute episodes. Cardiomyopathy may be the predominating feature in some cases and result in death.

Cerebral infarctions and myopathy occur in children, particularly when accompanied by hypoglycemia. Mean age at presentation is approximately 9 yr. Brain MRI shows distinctive changes related to multiple infarcts of various sizes.

The concentration of carnitine is reduced in serum as well as in muscle and liver. L-Carnitine deficiency can be corrected by oral administration of carnitine on a daily basis.

A similar clinical syndrome may be a complication of renal Fanconi syndrome because of excessive urinary loss of carnitine or loss during chronic hemodialysis.

611.6 Vitamin E Deficiency Myopathy

Harvey B. Sarnat

In experimental animals, deficiency of vitamin E (α-tocopherol, an antioxidant also important in mitochondrial superoxide generation) produces a progressive myopathy closely resembling a muscular dystrophy. Myopathy and neuropathy are recognized in humans who lack adequate intake of this antioxidant. Patients with chronic malabsorption, those undergoing long-term dialysis, and premature infants who do not receive vitamin E supplements are particularly vulnerable. Treatment with high doses of vitamin E can reverse the deficiency. Myopathy caused by chronic hypervitaminosis E also occurs.

Myasthenia Gravis

AUTOIMMUNE MYASTHENIA GRAVIS

Myasthenia gravis is a chronic autoimmune disease of neuromuscular blockade, characterized clinically by rapid fatigability of striated muscle, particularly extraocular and palpebral muscles and those of swallowing. It must be distinguished from congenital myasthenic
syndrome, a genetic disorder of receptors on the postsynaptic membrane of the neuromuscular junction and toxin-induced myasthenia, such as botulism (see below). The release of acetylcholine (ACh) into the synaptic cleft by the axonal terminal is normal, but the postsynaptic muscle membrane (i.e., sarcolemma) or motor end plate is less responsive than normal. A decreased number of available ACh receptors is as a result of circulating receptor-binding antibodies in most cases of autoimmune myasthenia.

A rare familial myasthenia gravis is an autosomal recessive trait not associated with increased plasma anti-ACh antibodies. One familial form is a deficiency of motor end plate acetylcholinesterase (AChE). Most congenital (familial) forms are postsynaptic defects. Infants born to myasthenic mothers can have a transient neonatal myasthenic syndrome secondary to placentally transferred anti-ACh receptor antibodies, distinct from congenital myasthenic syndromes (Tables 612-1 and 612-2).

**Clinical Manifestations**

In juvenile autoimmune myasthenia gravis, unilateral or bilateral but usually asymmetrical ptosis and some degree of extraocular muscle weakness are the earliest and most constant signs. Extraocular weakness is not confined to muscles innervated by just 1 or 2 of the 3 corresponding brainstem nuclei and is progressive. Older children might complain of diplopia, and young children might hold open their eyes with their fingers or thumbs if the ptosis is severe.
